CONTRIBUTORS

TO

VOLUME SIXTY-SIX.

Albert Abrams, A.M., M.D., of San Francisco, Cal.
Lewis H. Adler, Jr , M.D., of Philadelphia.
Harrison Allen, M.D., of Philadelphia.
R. W. Amidon, M.D., of New York.
Edward Anderson, M.D., of Rockville, Md.
R. Harcourt Anderson, M.D., of New York.
W. W. Anderson, M.D , of Newport, Ky.
P. M. Ashburn, M.D., of Philadelphia.
E. R. Axtell. M.D., of Denver, Col.
William S. Bagot, M.D., of Denver, Col.
A. B. Baird, M.D., of Oklahoma City, O. T.
M. V. Ball M.D., of Philadelphia.
Lewellys F. Barker, M.D., of Baltimore, Md.
J. Christian Bay, M.D., of Des Moines, Iowa.
A. L. Benedict, A.M., M.D., of Buffalo, N. Y.
Emma L. Billstein, M.D., of Philadelphia.
Louis Faugères Bishop, A.M., M.D., of New York.
William G. Bissell, M.D., of Buffalo, N. Y.
Thomas S. Blair, M.D., of Harrisburg, Pa.
M. H. Bochroch, M.D., of Philadelphia.
E. D. Bondurant, M.D., of Tuscaloosa, Ala.
Captain A. E. Bradley, U. S. Army.
Ludwig Bremer, M.D., of St. Louis, Mo.
Edward P. Brewer, M.D., Ph.D., of Norwich, Conn.
George S. Brown, M.D., of Birmingham, Ala.
F. E. Bunts, M.D., of Cleveland, Ohio.
Charles H. Burnett, M.D., of Philadelphia.
J. Abbott Cantrell, M.D., of Philadelphia.
William M. Capp, M.D., of Philadelphia.
C. C. Carter, M.D., of Columbus, Ohio.
Charles Cary, M.D., of Buffalo, N. Y.
F. Cauthorn, A M , M.D., of Portland, Oregon.
Charles V. Chapin, M.D., of Providence, R. I.
B. F. R. Clark, M.D., of Philadelphia.
S. B. Clark, M D., of Chicago, Ill.
Arthur H. Cleveland, M.D., of Philadelphia.
Solomon Solis Cohen, M.D., of Philadelphia.
Eugene F Cordell, of Baltimore.
John C. Da Costa, M.D., of Philadelphia.
Eugene A. Crouse, M.D., of Grundy Center, Iowa.
A. M. Davis, M.D., of Germantown, Pa.
John B. Deaver, M.D., of Philadelphia.
Theodore Diller, M.D., of Pittsburg, Pa.
W. A. N. Dorland, M.D., of Philadelphia.
L. A. Duhring, M.D., of Philadelphia.
Charles W. Dulles, M.D., of Philadelphia.
Isadore Dyer, M.D., of New Orleans, La
Seneca Egbert, A.M., M.D., of Philadelphia.

ORIGINAL ARTICLES.

APPENDICITIS.

Further Consideration of this Subject, with Tabulated Report of Cases not Previously Published.[1]

BY JOHN B. MURPHY, A.M., M.D.,
OF CHICAGO,
PROFESSOR OF SURGERY AND CLINICAL SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO; PROFESSOR OF SURGERY, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO COOK COUNTY HOSPITAL; ATTENDING SURGEON TO ALEXIN BROTHERS' HOSPITAL; CONSULTING SURGEON TO HOSPITAL FOR CRIPPLED CHILDREN, ETC.

IN order better to appreciate the trend of thought and practice on the subject of appendicitis at the present day, it will be greatly to our advantage to take a view of the work of the last five years. There has been no controversy in the history of medicine in which the struggle has been so intense between the surgeon and the physician as on that of appendicitis. Both parties have been honest in their convictions, and both equally positive that they are right. We naturally seek an explanation for this diversity of opinion as well as action, and the explanation is not difficult to discern. Differences of opinion as to the clinical course and probable results with operative and non-operative treatment have been almost entirely due to erroneous notions of the pathologic conditions.

Up to five years ago we had of the pathology of appendicitis practically no other but that of the post-mortem table; that has to-day been almost entirely superseded by the teaching of the operating-table. To-day we observe on the operating-table pathologic changes almost from the moment of their beginning until the destruction of the parts concerned is complete, whereas formerly we had deductions, and these very erroneous ones, from conditions that existed before the pathologic changes ensued which produced death. From results found post mortem we inferred the cause and course, and here was the source of error; to-day we observe the disease in the various stages of its progress from its inception to the final result. We are therefore preëminently qualified to arrive at a correct conclusion, inasmuch as our opportunities are so much greater for observing pathologic changes as they progress.

Now, on what points have the surgeon and the physician differed, and what has led to the diversity of opinion?

In 1888, when Kraft wrote his excellent monograph on appendicitis in *Volkmann's Vorträge*, it was the prevalent opinion of the profession all over the world that the vast majority of diseases in the sacro-iliac region were due to cecitis, an inflammation of the cecum or its surrounding tissues as a result of disease of that viscus, and it was variously known as typhilitis, perityphilitis, and cecitis.

Then, after Kraft's announcement, physicians gradually yielded point after after point until finally to day it is agreed that all except 2 per cent. of the inflammatory pathologic lesions about the caput coli are due to primary lesions of the appendix.

We may now regard the first point as practically settled.

The next argument advanced on theoretic considerations was that the appendix in inflammatory infections becomes swollen, and relieves itself by the discharge of its inflammatory products through its normal opening into the intestine, thus effecting a cure. What have we learned from observations at the operating-table? That in inflammatory lesions of the appendix the canal is rarely relieved of its inflammatory products in the way suggested, but is relieved by a necrosis of its wall and perforation. This is followed by the formation of an abscess and subsequent necrosis of the attached wall of the viscus to which it is adherent, the contents of the abscess escaping into the intestine.

The next contest was over the presence or absence of pus outside of the appendix in the majority of acute cases. Observation in operations has shown that in the acute stage pus is found outside of the appendix in 94 per cent. of the cases; that the existence of pus outside of the appendix does not demand a perforation of that organ for its production. That infection of the peritoneum and the formation of a peri-appendicular abscess may occur with an internal ulceration of the appendix and no perforation, I have shown by cases reported in the *Journal of the American Medical Association*, March 3 to 24, 1894. In that paper this pathologic condition was for the first time mentioned in the literature. While the profession was not prepared to believe that pus was present in the form of a circumscribed peri-appendicular abscess in practically all of the cases of acute appendicitis, it had been acknowledged for many years that in some cases abscess occurred around the caput coli, which emptied into the intestinal tract, and the patient recovered. We know now that this is the course in the very great majority of cases.

---

[1] Read before the Chicago Pathological Society, December 10, 1894.

The last and final questions, and those on which the controversy is still spirited, are (*a*) the pathologic changes produced by perforation of the appendix into the peritoneal cavity; (*b*) the likelihood of that perforation, and also perforation of the circumscribed abscesses about it into the peritoneal cavity; (*c*) the immediate and remote symptomatic and physical manifestations of the latter, and (*d*) the ultimate result of such rupture.

The pathologic changes produced depend, first, on the character of the material admitted into the peritoneal cavity, *i. e.*, whether the contents of the appendix or abscess consist of (*a*) pus or débris in which the staphylococcus predominates; (*b*) whether the streptococcus predominates; (*c*) whether the bacillus coli commune exists in its virulent or inert condition, and (*d*) whether the pus, in which any or all of these may have existed, has become innocuous; second, on the quantity of material admitted at one time into the peritoneal cavity; and third, on the condition of the peritoneum at the time of admission of pus.

I have observed in patients, and demonstrated experimentally, that pus in which the staphylococcus and the inert bacillus coli commune predominated could be free in the peritoneal cavity for a long period of time, and produce but very slight changes in the peritoneum, *i. e.*, that the intestine may be bathed in pus of this character for days without excoriating the endothelium of the peritoneum. I have observed a pint of pus of this character in the peritoneum of a patient in whom the history showed conclusively that it must have been present for five days, and upon opening the peritoneal cavity the normal gloss of the peritoneum of the bowel was still maintained. I have taken this pus and produced cultures with it, which demonstrated its character, and injected one dram of the pus as removed from the peritoneal cavity into the peritoneal cavity of animals, both with and without mechanical abrasion of the peritoneum, without producing the least unpleasant symptom, and no pathologic lesions were found on making an autopsy.

In cases of general suppurative peritonitis, as a result of appendicitis, that have been under my observation, in which the normal glistening appearance of the peritoneum was present at the time of operation, the patients recovered, and inoculations of the pus into the peritoneal cavity of animals produced no unpleasant symptoms or lesions. When I find that the pus has not abraded the peritoneum, even though the surface of the latter has been covered with the former for a length of time, I consider the case a favorable one.

Note how this contrasts with the appearance in the abdomen when the streptococcus predominates. Here we find that, within a short time after rupture into the peritoneal cavity, the peritoneum in contact with the infectious material is entirely denuded of its endothelium, resembling the condition produced by a cantharides blister. The quantity of pus is always small, rarely exceeding a few drams, with here and there flakes of lymph. The bowel is distended and paralyzed; peristalsis has ceased. Inoculations with this pus produce the same condition; the red and angry appearance of the intestine I now recognize as a signal of the gravest importance, as, practically, all of my cases in which this condition was present terminated fatally.

The septic conditions due to the bacillus coli commune produce about the same physical manifestations as those of the streptococcus. The quantity of material discharged into the peritoneal cavity is of great significance; if it be small the intestines and omentum rapidly circumscribe it and protect the general peritoneal cavity from invasion. If it be large, and if it be irritating and poisonous, it may abrade the peritoneum of its endothelium as boiling water would, quickly, and be followed by a rapid absorption, causing death in a few hours. I have had only one case of this class, in which an abscess of considerable size ruptured into the peritoneal cavity. Within two hours the extreme symptoms of shock were present, and in twelve hours the patient succumbed. If a large quantity of pus of a low septic character be admitted into the peritoneal cavity it may remain in that cavity for days, and produce but slight changes. Finally, from some cause, this material, which had been innocuous, suddenly produces grave conditions and symptoms.

It is a matter of deep-rooted belief that a peritoneum that has been irritated repeatedly by the presence of a tumor, by the close proximity of an accumulation of infectious material, finally attains an increased resistance against infection, *i. e.*, the peritoneum of a patient who has suffered from the presence of a large and movable tumor will tolerate much more manipulation than a perfectly normal peritoneum, and that the peritoneum in the neighborhood of an old circumscribed abscess is more difficult to infect than a healthy peritoneum.

There has been a great difference of opinion as to the symptoms of appendicitis and the relation of the symptoms to the pathologic condition within. This diversity will continue until our power of differential diagnosis is very much increased. From a train of symptoms and signs in the early stage it is impossible to say just what is the exact pathologic condition. We can say, however, that it is a disease of the appendix in some stage of its development.

The symptoms of appendicitis are (1) a sudden pain in the abdomen; (2) shortly followed by nausea and, perhaps, vomiting; (3) local tenderness over the site of the appendix, and most frequently in the right iliac region; (4) elevation of temperature. These symptoms, occurring in this order, without a previous history of genito-urinary infection, or of a lesion of the gall-tracts, or Pott's disease, indicate with almost uniform regularity appendicitis. They do not indicate that the appendix is gangrenous, or that there is a simple catarrhal appendicitis. They do not indicate whether it has perforated or has not perforated; nor whether the cause is an infection with the staphylococcus, the streptococcus, or the bacillus coli commune, or the presence of a fecal stone, or of a foreign body. They do not indicate whether it is a stenosis of the appendix or an appendicitis obliterans, but merely that it is an appendicitis or acute disease of the appendix.

The physical manifestations, the presence or absence of induration, tumefaction, edema of the wall, tympanites, etc., aid in the differentiation of the various pathologic conditions present in the more advanced stage; but all of these are absent or comparatively worthless in the early stage.

The etiology, which was for a long time a subject of contention, is now practically agreed upon. It was very difficult to eradicate from the professional mind the deep-rooted erroneous belief that in a great majority of cases appendicitis was due to foreign bodies admitted into and retained in the appendix, as grape-seeds, cherry-stones, fragments of bone. Only 2 per cent. are cases with foreign bodies, and fecal stone in 38 per cent. To indicate the causes of appendicitis I will use the same classification employed in my article of March 3, 1893:

1. Simple pus-infection, producing the catarrhal variety.
2. Extensive infection by the bacillus coli commune or by pyogenic microbes, producing gangrene of a greater or lesser portion of the appendix.
3. Pressure-atrophy with infection of the appendix (*a*) by fecal concrement, and (*b*) by foreign bodies.
4. Retention-accumulations (*a*) from cicatricial contractions, stenosis, and obliteration, and (*b*) from occlusion by an enterolith or foreign body.

From the reports of autopsies collected I find that in 70 per cent. of the cases there were perforations of the appendix. Of my own cases in which the appendix was removed there was 87 per cent. Simple primary catarrhal appendicitis, if it exists, is rarely brought to the attention of the physician and still less frequently to that of the surgeon. Of 194 cases reported we had but one of this variety. A catarrhal inflammation in which the more serious form of appendicitis had previously existed is not uncommon.

The question of greatest practical importance to the surgeon and physician is the diagnosis. Can we determine when appendicitis is present, and can we determine the pathologic conditions that exist in the abdomen at any given time in the progress of the disease? To the former we must with positiveness answer in the affirmative; to the latter an equally forcible negative must be given; that is, we can say from the symptoms that a lesion of the appendix exists; but we cannot say, in most cases, how extensive, how dangerous, and how far-reaching the effects of that appendicitis may be, and still less can we say in any given case how soon the life of the patient may be greatly jeopardized by the disease which at the moment has apparently no grave danger.

If we were able to determine in the early stage, from the symptoms, physical signs or clinical history of a given case that it is going to take a favorable or an unfavorable course, we would regulate our treatment accordingly. Unfortunately, there are no symptoms present in the dangerous cases admonitory of their fatal termination until the patient has passed beyond the condition in which an operation offers reasonable hope of a recovery. The question to be answered is, When should we operate? The so-called conservative answers: "Operate on the collapsed cases; the cases that present symptoms of fulminating peritonitis; the cases that are taking an unfavorable course; the cases that appear to be progressing rapidly to destruction under medical treatment."

The surgeon must take a positive stand, and answer "No" to each of these rules. It is admitted that 50 per cent. of the fatal cases terminate before the end of the sixth day, many on the fourth, and a smaller number on the second. The surgeons who wait until the sixth day must, therefore, expect to have a mortality of 50 per cent. of all the cases that would die without operation. I believe the proper position for the true, earnest, and advanced medical man is expressed by the eminently scientific and truly conservative physician, Dr. Norman Bridge, in the following words: "Appendicitis is one of the most frequent and dangerous of the inflammatory diseases in or about the peritoneal cavity. We do not know the line between proper medical treatment and the demand for surgical interference, and I rather despair of finding it. The medical man is practically powerless to control the destiny of the patient. It is always a surgical disease, and the mortality should be materially lessened by skilful surgical treatment."

Would you delay operation on a case that is progressing favorably? By that I mean a case in which the temperature is not above 99°, the pulse not above 80, the expression good, the abdomen presenting no alarming signs? No; I have seen cases of this class go to the third, the fourth and the fifth day with all of the most favorable symptoms that could well be imagined, and on the sixth day die. From what? From a suppurative peritonitis that had existed all the time, as shown by the pathologic changes found in the peritoneum.

We have no sign, symptom or combination of signs and symptoms that indicate, with any degree of certainty, suppurative peritonitis in the cavity stage.

It may exist and the free peritoneal cavity contain drams of pus with a temperature of 99°, a pulse of 80, and a good facial expression. Note the following case that occurred in the practice of Dr. James G. Berry:

G. F., aged nineteen, weighed 220 pounds. On the morning of September 8th, after breakfast, he was attacked with a severe pain in the abdomen, followed shortly by vomiting, and the pain and discomfort were sufficient throughout the day to prevent the man from attending to his work. He remained about the same during the night, and the following morning at 10 o'clock, twenty-six hours after the onset of pain, he walked a couple of blocks to the drug-store and consulted the druggist concerning his trouble, who advised him to see a doctor, and he was seen by Dr. Berry at 3 o'clock, and the diagnosis of appendicitis was made. His pulse, when seen by Dr. Berry was 140, and temperature 102°. There was no tympanites; there was increased local tenderness over the region of the appendix; peristalsis was absent; the patient's countenance was good, and he expressed himself as tolerably comfortable. At 4 o'clock, assisted by Drs. Berry and McQuaig, I performed celiotomy. On opening the peritoneum pus flowed out. There were no adhesions whatever between the intestines; the appendix was free; a fecal stone protruded from an opening in the side of the appendix, where it produced pressure-atrophy perforation. The abdominal cavity was sponged; pus was found down in the pelvis; drainage was by gauze. The normal gloss of the intestine was not disturbed in the least by the presence of the pus, and the surface was not even red. The patient made an uninterrupted recovery.

It will be noted that the operation was performed thirty-three hours after the onset of the symptoms, and but a few hours after the patient had been walking in the street with a suppurative peritonitis. What would have been his condition if the operation had been delayed twenty-four or forty-eight hours? The answer is self-evident.

A retention-appendicitis, on the other hand, may produce a temperature of 105°, or even higher, enormous tympanites and a pulse of 140, an anxious facial expression, and all of the so-called classical symptoms of peritonitis, and the peritoneal cavity be free from infection. These are extreme pictures, but they occur.

When should we operate? As we are unable from the signs and symptoms to determine the exact pathologic condition, are we justified in allowing the probability of fatal conditions to continue for such a period of time without action as would place the patient beyond the possibility of rescue even by operative procedure? No! Until such time as the physician is able to determine the exact pathologic condition and danger in the individual case (and, indeed, we must now consider that time far distant), he is not justified at the peril of the patient's life in restraining the surgeon from acting. It must be conceded by all that an operative procedure, in competent hands, is in itself one involving very little risk, while the continuation of the pathologic processes in many cases greatly jeopardizes the life of the patient. There is only one safe position to take, and that is, in every case in which a diagnosis of appendicitis is made the operation should be immediately performed. It is true that many cases can recover without operation; but we cannot differentiate, in the early stages, which cases are going to be the favorable ones. It is further true that the earlier the operation is performed the less the danger to the patient and the greater the ease of removing the appendix. In a great majority of cases, if an operation be performed within forty-eight hours after the onset of the symptoms the appendix is not yet ruptured, and can be removed without pus-infection of the peritoneum, an advantage of which even the boldest surgeon is pleased to avail himself. The following case in the practice of Dr. J. H. Hoelscher is a beautiful illustration of this class:

Date of operation, November 10, 1894. Operator, Dr. J. B. Murphy with Dr. Hoelscher. Diagnosis, appendicitis.

Miss T., aged sixteen, was perfectly well up to 4.30 P.M. November 9th, when she was attacked with pain in the abdomen, which persisted and increased in severity, compelling her to go to bed. She began to vomit at 8.30 P.M., and vomiting and pain continued through the night and up to the time of operation. At 11.30 that night, when seen by Dr. Hoelscher, the temperature was normal. The diagnosis of appendicitis was made. At 8 A.M., November 10th, the temperature was 99.5°, the pulse 90; at 11 A.M., the time of operation, the temperature was 100°, the pulse 110. There was great tenderness over the region of the appendix; but insensitiveness in other parts of the abdomen. There was no tympanites; peristalsis was absent in close proximity to the appendix; the expression was good.

Operation was by the lateral incision. The appendix was covered entirely by visceral peritoneum adherent to the posterior surface of the cecum up on to the ascending colon. The end was enlarged to half-an-inch in diameter, and contained no fecal stones, but was full of pus; gangrene of the mucous membrane was commencing; lymph-flakes existed in the outer wall of the appendix. The appendix was ligated and removed without rupture, the peritoneum sewed over, and gauze drainage inserted. The patient made an uneventful recovery.

In the later stage, if the surgeon is unfortunate enough to be called at that time, when the peritoneum is flooded with pus, and the patient in collapse, it is his duty to perform the operation and give the patient the advantage of the small percentage in his favor in this forlorn condition.

The rule, first, last, and always should be: Operate in every case of appendicitis, promising or unpromising, at the earliest possible moment. What operation shall we perform? The incision should be made a little toward the median line from the highest point of induration, parallel to the rectus; the muscular layer should be separated with the handle of the scalpel parallel to the course of the fibers, as advised by McArthur and McBurney, thus lessening the liability of hernia. The opening must be ample to allow the surgeon to perform the work within with ease. In the early cases the appendix should be removed, as the adhesions are friable and permit of the appendix being readily separated and drawn into the field. The parallel band of fibers on the cecum opposite its mesentery can always be followed to the position of the appendix, and is an infallible guide to its location. If the peritoneal cavity be opened before the abscess is reached, as is always desirable in the early stage, a thorough packing of gauze should be made around the induration to prevent the pus from entering the unaffected portion of the peritoneum. This I consider of very great importance, and I make an effort to enter the peritoneal cavity just to the side of the adhesions, so as to open the unaffected portion of the peritoneal cavity before I open the abscess; in that way the adhesions may be located, and the packing well placed, so as to thoroughly protect the peritoneum before the adhesions are torn.

In the later cases, that is, from the seventh day on, I consider it advisable to open directly into the abscess when adhesions are present, drain the abscess, remove the fecal stone, if one be present, and make no effort to remove the appendix. The appendix in the acute cases should be simply ligated with chromicized catgut; no effort should be made to top-sew it or bury it in the cecum. Occasionally there will be a fecal fistula, but that closes in a very few days itself.

In the cases of appendicitis operated on in the intermediate stage, *i. e.*, between the attacks, a cuff should be made of the peritoneum of the appendix, peeling the peritoneum back one-half inch or more; the muscular layers should be ligated and the cuff drawn back over the stump of mucous membrane and ligated. The pus should be carefully sponged out of the cavity, and no water or disinfecting solutions used; do not waterlog the peritoneum, as it is sufficiently taxed in taking care of the pus without this additional labor. A glass drain and a gauze drain should both be used in all cases in which pus is present at the time of operation or in which there has been a recent attack of appendicitis. The drain can be removed in eight or ten days, as the cavity fills up from the bottom.

This, in short, is an outline of the procedure I follow. All of the minor details cannot be mentioned here. There is no operation in the peritoneal cavity in which the patient's life is so completely in the hands of the operator, in which the errors of doing too much or too little work would be so likely to result fatally, as in the operation for appendicitis, with its multiform and complicated pathologic conditions. The result depends in a very great degree on the extent of the invasion, and the latter upon the period of time that has elapsed since the onset.

In speaking of results, I do not mean the results in recurring appendicitis, the simplest and least dangerous variety of all; I mean the results in all cases, from those of general suppurative peritonitis as a sequence of appendicitis, to those of the simplest catarrhal variety.

There is a growing tendency in the profession to shirk the responsibility of operating when the dangers are great, *i. e.*, to defer operation on the most dangerous cases and advocate operation on the obliterated or stenosing recurrent varieties in which there is the least danger to the life of the patient from the disease. We must not swerve from our obligations to our patients, but should make every effort to rescue them regardless of the praise or condemnation bestowed upon us.

In reporting cases it is the duty of every operator to classify or mention in detail the important or common symptoms of each individual case in a tabulated form, and give an abstract of the history and pathologic conditions, that the analytical mind in reviewing the results obtained by individual operators may be able to explain the cause of success or failure when the operator himself is not able to do so. It is, therefore, the duty of every surgeon in writing on this subject to give sufficient details of his cases to enable the reader to judge whether they were of the grave or mild variety; whether they were all cases of recurrent, simple, adhesive appendicitis, or whether many of them were of the gangrenous, perforative, and malignantly infectious variety, with the peritoneum extensively involved.

I shall endeavor to give a short outline of the various conditions found in operating for appendicitis.

1. When the abdominal wall is infiltrated, and the abscess is opened without opening the unaffected portion of the peritoneum, there may be (*a*) a small circumscribed abscess, with the appendix forming part of the wall; (*b*) a small abscess, with a tract leading to a larger abscess more deeply; (*c*) a large abscess filling the iliac fossa, containing fecal concretions, or a gangrenous appendix floating in the pus, all closed in with firm adhesions. (This condition never exists in the early stage, and in this class of cases the adhesions protecting the peritoneum should never be broken to remove the appendix.) (*d*) There may be multiple abscesses, with no connecting sinuses. This is a comparatively rare condition. In one of my cases a second abscess was not opened, and the patient died of pyemia four weeks later. (*e*) There may be an abscess in the opposite side of the abdomen; it usually appears in the same relative position, to the left anterior superior spinous process, as the abscess does to the right. There is no connecting sinus. It never occurs in early cases, and is more commonly found a week after operation and three or four weeks after the onset of attack, and should be opened and drained.

2. In another class of cases, when the peritoneum is opened and no adhesions to the anterior abdominal wall are found, a circumscribed abscess may be found situated on the posterior wall of the abdomen, the appendix and pus surrounded and walled in by adherent omentum and intestine. This is the most common condition found in the early stage. The location of the abscess may be near the median line near the margin of the pelvis, close to the crest of the ileum, over the kidney posterior to the cecum, or on the margin of the liver, as in two cases. The occurrence of a suppurating appendix on the surface of the liver or adherent to its margin is due to the congenital deformity and malposition of the cecum, so perfectly described by Cushmann, and the distention of the colon with gas does not aid in making a differential diagnosis between appendicitis and cholecystitis. Still, the most frequent location for the appendix is in the neighborhood of the McBurney point. The exact position of the appendix can be found by following the white fibrous bands along the convex surface of the cecum to the base of the appendix. In all of these cases the field of operation should be thoroughly protected by carefully packing with strands of iodoform-gauze, retaining the ends outside. The adhesions are separated, the pus sponged out, and the appendix liberated from its adhesions; a ligature is then placed on the appendix, and one on its mesentery. In all the cases in which the peritoneal cavity is opened directly the appendix should be removed. When the appendix is situated above and behind the cecum, in close proximity to the liver, the induration can be detected behind the cecum, and must be reached by pressing the cecum forward, packing around, and opening the abscess, locating the appendix, and removing it.

3. When the abscess is circumscribed in the pelvis, and the appendix is found hanging over the brim, or attached to the uterus, the tubes, or the ovaries, the appendix is located by following the bands on the cecum; pus should be sponged out, the appendix amputated, and a long glass drain inserted.

4. In another class of cases the peritoneal cavity will be found to contain a large quantity of free pus with no limiting adhesions, and the bowel may be smooth and glossy, not in the least congested or eroded of its endothelium. All of these cases recover. On the other hand, the bowel may have a livid, blistered appearance, entirely excoriated of its endothelium, and very much distended, showing a paralysis of its muscular walls. The great majority of such patients die. In either of the cases stated the appendix may be adherent or free; it is usually perforated and gangrenous. In both, the appendix is located by the fibrous bands on the cecum or by the sensation to touch by its swollen, hard, and enlarged condition; it must not be confounded with the indurated omentum. Extensive drainage, both of glass and gauze, should be employed, and no irrigation.

5. We find a class of cases in which there is a small quantity of pus located around the appendix, with partial adhesions protecting the peritoneum, and with flakes of lymph extending some distance. This condition may be caused by a perforation of the appendix; by gangrene of the mucous membrane, local or general, without perforation; by a simple ulcer of the appendix without perforation; by accumulation and retention of muco-purulent material in the appendix, with only an abrasion of the mucous membrane of that organ.

6. Specific ulcers in the appendix without perforation or infection of peritoneum, as (*a*) tuberculous, of which I have had one case with recovery; (*b*) typhoid, three cases, all recovered. Both of the latter conditions produced all the acute symptoms—pain, vomiting, tympanites, and elevation of temperature. In these cases, when the appendix is located at the time of operation, it will be found very much enlarged at the seat of ulceration, with the distal end distended with accumulation.

7. There is a class of cases in which the canal of the appendix is partially or completely obliterated or stenosis of the canal is produced sufficient to cause retention of material in the distal end, causing recurrent attacks. In one of the cases of this kind

194	" 15	J. T. S., M. 25	"	1	...	...	...	...	...	1	...	23 h	...	...	...	...	...	...	...	...	1	...	...	...	1	...	1	1	1	102	...	...	...	Wall of appendix very much enlarged: full of pus; mucous membrane gangrenous; ready to perforate.	

there was a fecal stone entirely surrounded by connective tissue, the mucous membrane having been completely destroyed and the canal obliterated in a previous attack; there were no adhesions around the appendix. In many other cases portions of the canal were found obliterated, and in others a stenosis or narrowing of the canal; the latter is the most annoying variety, as there are frequent recurrences of attacks, and the patient is rarely ever free from pain or sensitiveness in that region. As far as I can learn from the literature, the credit belongs to Dr. Henry O. Marcy, of Boston, for being the first to perform the operation of appendicisectomy in the intermediate stage for the relief of this class of cases. The operation was on Dr. Samuel B. Nelson, November 9, 1886, and the report was published in the *Boston Medical and Surgical Journal* at that time. The patient recovered, and left the hospital in eighteen days.

8. *Appendicitis stercoralis.* In this class of cases there is a large accumulation of feces surrounded by mucous or muco-purulent secretion. The attacks of pain are severe and recur frequently. They are usually accompanied by a temperature not exceeding 100° or 100.5°, and vomiting is a very pronounced symptom. The attack resembles one of intestinal retention, as frequently a movement of the bowels cannot be produced for four or five days. The cause of the symptoms of intestinal obstruction has not been clearly explained, but I believe them to be reflex phenomena, as we find exactly the same condition produced in obstruction of the ductus cysticus with gall-stones. The appendix in cases of this kind is very much enlarged at the distal end, small at the proximal end; its mucous membrane is thickened, and it contains a large quantity of hardened feces.

The mortality in my cases, including all grades, and operating on every case of appendicitis, favorable or otherwise, which came under my observation, is 9.6 per cent. The total number of cases operated on to date is 194. The table on the preceding page is a tabulated form of the cases operated on since my publication, March, 1894.

In the literature of this subject I wish to call attention particularly to the contributions, each presenting various phases of the disease to greater advantage than the other, of Kraft, McBurney, Maurice Richardson, Bryant, Shrady, Wyeth, Sonnenburg, Robert T. Morris, Senn, and McArthur.

A Sign of Intestinal Occlusion Due to Incarceration or Torsion.—At the recent French Congress of Surgeons, Gangolphe (*La Méd. Mod.*, No. 83, p. 1292) called attention to the occurrence of a sero-sanguinolent effusion into the peritoneal sac in cases of intestinal occlusion due to strangulation or torsion. He considers the detection of this sign as an urgent indication for immediate surgical interference.

SOME PRACTICAL SUGGESTIONS ON THE TREATMENT OF WOUNDS.

By WALTER L. PYLE, A.M., M.D.,
OF WASHINGTON.
SOMETIME RESIDENT PHYSICIAN OF THE EMERGENCY HOSPITAL.

My object is to offer some practical suggestions, deduced from personal observation, and with special reference to the kind of wounds that occur in the cases colloquially classed as emergency cases.

In *wounds of the scalp*, after carefully preparing the hands, the first steps in treatment are the shaving of the neighboring field and thorough irrigation of the wound with a heated 1 : 2000 solution of mercuric chlorid, using from four to sixteen fluidounces. All foreign bodies should be removed, and the wound should be explored with the finger carefully, seeking the extent of the injury and the amount of damage done to the periosteum or bone. Then further irrigation of the wound with the warm mercuric-chlorid solution should be practised. This, in a measure, will check oozing.

The next step is the control of hemorrhage, which is often profuse, owing to the extreme vascularity of the parts. By following up with a hemostat, a sterilized cotton or gauze sponge wrung out in the mercuric-chlorid solution, the bleeding point or points can generally be located and controlled. This is the most satisfactory mode, and should always be practised in preference to such unskilful and awkward procedures as continued compression (often followed by sloughing), and the uncleanly filling of wounds with substances or solutions having hemostatic properties. Twisting the smaller vessels will satisfactorily close them, but the larger ones must be ligated. Silk is always attainable, is strong and safe, and can be readily sterilized by immersion in boiling water, and hence offers the best ligature-material in the cases under discussion.

The next step is the approximation of the edges of the wound. Although I have never seen sutures, properly applied, used in a scalp-wound to a disadvantage, we may consider them dispensable when there is little gaping, rendering the wound less liable to infection, should there be any laxity in the antiseptic precautions.

As to suture-material, silk again is always readily obtained and easily sterilized, and offers the best all-round material we have. Horse-hair kept in a mercuric-chlorid solution is the most satisfactory suture; but in an urgent case is not always at hand.

The interrupted suture is the best in scalp-wounds, as good apposition can always be obtained. It can be tightened without causing undue puckering, thus mechanically checking any oozing. It is easily removed. I have often tried the subcutaneous suture, but without as good results as with the interrupted. If there is little gaping, as when the wound is in the direction of the muscle-fiber, it can always be dressed, and sufficient coaptation secured either by adhesive strips over sterilized gauze or by some form of collodion dressing. When sutures have been necessary the best dressing is that of collodion, either with iodoform or carbolic acid, or simple collodion. The collodion can be readily removed, even even if tightly adherent, by the application of ether. In three or four days the sutures should be removed and the wound again covered with collodion, giving instructions to the patient to let it wear off.

Bandages can usually be dispensed with, and only in cases with much laceration and contusion are they at all necessary. They are most inconvenient, and many cases of persistent headache are directly attributable to their unnecessary application. The continued compression of a bandage too often exerts a deteriorating influence on the healing-process, and may cause sloughing of the part. Owing to extreme vascularity wounds of the scalp heal readily, show little tendency to slough, or to become infected, except when treated under primeval methods.

If digital examination shows the periosteum to be injured, or its continuity broken, it should be united by a continuous suture of fine silk. If there is much denudation of the bone and overlying tissue the wound should be left open and allowed to heal by granulation, as there is likely to be necrosis and exfoliation of the bone.

The most satisfactory dressing in cases like this is one of iodoform-gauze covered by successive layers of wet mercuric-chlorid gauze, over which is placed a piece of mackintosh to retain the moisture, thus rendering the wound constantly safe from infection, and thus dispensing with continued irrigations, which are extremely painful to the patient. It is hard to conceive of a case, particularly in urban practice, in which a mercuric-chlorid solution, some silk and boiling water are not readily obtainable. These are the sole requisites for aseptic treatment, and with them pus is almost unknown in the healing-process. With these simple precautions the formerly common abscesses of the scalp and their possible frightful results, together with erysipelas, etc., will be eliminated. In fact, in my experience at the Emergency Hospital, where wounds are received under the most unfavorable conditions, often many hours old, I have never seen a case of extensive suppuration beneath any of the several layers covering the cranium.

Wounds of the face are annoying on account of the frequent subsequent disfigurement due to cicatrization or scarification. In suturing wounds about the eyelids the closest apposition should be obtained and the finest suture material used. The sutures should not be tightened, as the slightest puckering about the eye will produce a decided deformity. The tissues of the face are very vascular, and the continuous or subcutaneous suture can be used to an advantage.

Wounds involving the buccal mucous membrane are also prone to produce marked disfigurement, and in suturing, the object is to unite the mucous membrane in such manner that the dividing pink line on the lips shall be maintained in regular continuity. It is of course difficult to keep these wounds clean and aseptic, owing to the entrance of particles of macerated food and saliva, but fortunately the results of such infection seem to be of little consequence, and we can always expect these wounds to do well. Potassium permanganate and hydrogen dioxid are frequently used with seeming benefit as mouth-washes. Attention to the anatomic distribution of the arteries of the scalp and face will always be of advantage, as they are all superficial and can be controlled temporarily by digital compression until a hemostat can be applied.

In extensive wounds of the face one must be wary of subsequent facial palsy, due to severance of the branches of the seventh nerve, and warn the patient of its frequency; thus relieving himself of unjust blame.

We must frequently trust much to granulation and not attempt to draw portions of the surviving tissue together, often with the result of producing marked deformity. A subsequent skin-graft is often of service after granulation is well advanced. If there is much contusion or laceration of the tissues warm boric fomentations are advisable.

Continued boric fomentations offer the best treatment for what is commonly known as black eye. There also seems to be an anodyne property in the heat conveyed to the part in this manner, besides its usefulness in materially reducing inflammation.

The only point I wish to emphasize in treatment of *wounds of the upper extremity* is to avoid compression by bandages, particularly about the elbow-joint, where much swelling must be expected after contused wounds. Circular compression is always dangerous to a limb, and, if a bandage must be applied, the application should be made over two splints, diametrically opposite, thus utilizing lateral compression only. One should search always for the ends of divided or severed muscles, tendons, and nerves, and under no circumstances close a wound until the ends have been united, as retraction is constantly taking place, thus rendering the union more and more difficult. Here again we should use copious irrigation of the warm mercuric-chlorid solution, and, if there is much laceration and contusion, the wet dressing.

In the treatment of *wounds of the fingers* there is seldom any occasion for immediate amputation.

We should save as much tissue as possible, dress the injury with wet mercuric-chlorid dressing; then, after several days, if the extremity shows no signs of vitality, the question of amputation may be considered, although it has been my plan to allow the dead tissue to slough off and the wound to heal by granulation. While this is not a clean, neat procedure, it is entirely safe under strict antiseptic precautions, and invariably saves tissue that is of incalculable value in the case of the fingers. I have had a case of complete severance of a finger by a bread-cutter, and have united the severed portion to the stump by silk sutures, and in a short time had complete restoration of the part. Several of my medical friends have cited similar instances, and I mention them here to impress the value of economy of tissue. It must be remembered that under new methods the old bugaboos of surgery—gangrene, erysipelas and pyemia, are relics of the past, and that in a case like that stated, if satisfactory union did not take place there would be plenty of time for amputation of the vitalized part after several days of observation.

In stab-wounds, or, in fact, in any penetrating *wounds of the chest or abdomen*, the surrounding cuticle should be immediately shaved and scrubbed with mercuric-chlorid solution, and a large, bulky dressing of mercuric-chlorid gauze and sterilized cotton applied. Then, if entrance into either of these cavities is deemed advisable, it can be done safely and in a short time. It is well not to probe here, as the mere act of probing discloses little and may disturb an all-important clot or introduce sepsis.

The same admonition may be made in regard to immediate irrigation, which may disperse a clot and start an alarming hemorrhage which is not easily controlled as in the former instances. We should always strap the chest in wounds of any kind in that locality, and strive to keep the respirations down with successive doses of morphin. It is also well to apply an abdominal binder in wounds of the abdomen and to keep the patient in a supine position. All treatment in this kind of cases is expectant, as any alarming symptoms indicative of internal hemorrhage demand active operative interference. It is well to bear in mind the possible occurrence of secondary hemorrhage, which may happen at any time during the first fortnight, during which time the patient should be kept quiet and treated expectantly.

To summarize: We rely much on the fixation of the chest by adhesive straps, or even by a plaster jacket in wounds of any nature about the thoracic cavity, and likewise with the binder in abdominal cases.[1]

Transfusion is seldom of any avail after the occurrence of extensive hemorrhage, and should be practised only with great caution. External heat by water bottles, or by heated blankets, hypodermic stimulation by strychin sulphate to a maximum of gr. $\frac{1}{10}$, ergot, brandy, digitalis, ammonia, etc., autotransfusion by bandaging the extremities, and rectal injections of a warm saline solution will generally suffice and exert none of the untoward or dangerous effects of the transfusion. It is when these procedures prove of no avail that operative interference is peremptorily demanded, as therein lies the only hope of avoiding a fatal issue.

Bullet-wounds of the extremities should always be thoroughly irrigated and packed with an iodoform-drain, making the drainage complete from the wound of entrance to that exit, if possible. Hemorrhage is not an important factor in bullet-wounds, as the elastic bloodvessels generally escape injury. When, however, there is severance of a bloodvessel it must be sought for or dissected out and ligated. As it may be the main vessel of the limb, the pulse should always be sought below the seat of injury; its absence indicates stimulating treatment, to maintain the vitality of the member, and expectant preparation for amputation if sufficient anastomosis is not established. Here, also, all muscles, tendons, and nerves, should be united as soon as discovered, which may not be till use of the member is attempted.

Relative to the bullet itself, I think we should never make any extraordinary effort to locate it. If, after ordinary probing, it is not discovered, the wound may be allowed to heal by granulation, and if it causes any subsequent trouble, the pressure, pain, etc., will locate it, and it can be readily removed after the original wound has entirely healed.

If signs of suppuration are prominent in the injured member, free incision along the suppurating tract should be made and open drainage established. This, together with the wet mercuric-chlorid dressing or antiseptic fomentations constantly applied, will usually suffice, and amputation for suppuration in a bullet-wound should be a very rare indication. Administration of quinin and stimulation are always indicated to offset the entrance of sepsis systemically.

A limb should always be splinted in which there is an extensive wound of any kind, thus gaining fixation of the parts, and markedly augmenting the efforts toward restoration. In the furtherance of this we need to remember to make the splints wide enough to avoid circular compression. Elevation of the affected member will always ameliorate pain and lessen hemorrhage. The possibility of secondary hemorrhage must again receive consideration.

In treating poisoned wounds the points to be borne in mind are the relief of pain and swelling, which are temporarily severe, and the antidotal treatment of the poison. Anodyne preparations and ammonia-water are efficient in insect-stings. The application of either warm fomentations, or, what seems better, cracked ice, will be sufficient to reduce the swelling.

---

[1] The wisdom of this limitation of respiratory movements is demonstrated in a case of rupture of the lung which I reported in THE MEDICAL NEWS, February 24, 1894.

Most venom has been shown to be a decidedly cardiac depressant, and its effect is probably due to a process similar to ptomain-poisoning; hence the use of the intermittent ligature in *snake-bite*, to allow the entrance of the poison gradually, by which means the leukocytes and other like constituents of the blood can combat it successfully, and not be suddenly overcome by it. Stimulation to excess by means of alcohol (always at hand), strychnin, digitalis, strophanthus, or nitro-glycerin, should be practised, and the wound cauterized or excised.

Surcharging the blood with oxygen by inhalations of the pure gas, or by hypodermic administration of some readily deoxidizable substance as potassium permanganate, is a method worthy of trial.

The idea of any one specific as efficient in these cases of venomous bites is unworthy of comment, as the treatment must be conducted on the general principles laid down by observance of the physiologic action of the venom.

In treating *animal bites*, when there is a distinct wound observable, antisepsis should be prominent. The cautery, actual or chemic, is demanded. Many cases reported as hydrophobia are merely examples of general systemic infection from a local focus of sepsis, made possible by some primitive and uncleanly treatment of the original wound. With but few exceptions all such wounds under my observation have been filled with the hair of the dog, soot, ham-fat, and particles of decayed food, and saliva from the mouth of some person who has practised sucking the wound. This is the result of superstition among people presumably intelligent.

The medical consultant should always treat this kind of wound as any other, and be rigid in irrigation and antiseptic dressing.

A word regarding suppurating wounds of long-delayed union. I have found that after using the ordinary stimulating applications without avail a solution of zinc chlorid, forty grains to the fluidounce of water, will bring about the desired effect. In making the application of this solution to the suppurating or sluggish tract or cavity, all the neighboring healthy tissue should be carefully protected from its caustic action.

In a case of laminectomy belonging to Dr. James Kerr, under my observation, and which I reported in the June *Annals of Surgery*, an application of this solution was the means of healing a suppurating tract that had long resisted all treatment.

As to *phlegmons* of the hand or finger, the proper treatment is early incision, curettement, and a wet antiseptic dressing, preferably of warm mercuric-chlorid gauze constantly renewed several times a day.

No. 1701 H Street, N. W.

THE FILTRATION OF WATER.

By CHARLES V. CHAPIN, M.D.,
SUPERINTENDENT OF HEALTH, PROVIDENCE, RHODE ISLAND.

As the water-sheds from which the supplies for our cities are drawn become more and more thickly populated, the danger of pollution of the waters obtained from them will progressively increase. The building of sewers is going on at a rapid rate in all our cities and larger towns, and even in many small villages, and unfortunately it is the too-common practice to discharge them into the nearest water-course, whether it be used for drinking-purposes or not. The water-carriage of sewage into a stream serving as a public water-supply is the most efficient mechanism that could be devised for the dissemination of such diseases as cholera and typhoid fever. Even when sewers do not discharge into a river, a few privies on the bank, or a few overflowing cesspools, have been known to be sufficient to cause a widespread epidemic. And though all patent sources of pollution may be removed if the banks of a river or a lake have a considerable population, an accidental pollution may be followed by disastrous consequences. Thus in Providence, in 1888, an epidemic of typhoid was caused by the careless throwing of slops, containing excreta of a patient, upon the banks of the river from which the water-supply of the city was taken. Though much more than at present might be done to restrain this pollution by legal means, yet it is certain that at the best the danger of polluted waters will increase rather than diminish. The remedy that has hitherto usually been offered by sanitary engineers is to seek a new and a purer source of supply; but this is manifestly impossible in many cases, and in others, while perhaps feasible from an engineering standpoint, the great cost of the improvement would preclude its adoption. There is little doubt that many of our cities make use of water from a source that is more or less contaminated, and that there is little likelihood that these sources will be abandoned. The more practical question is: Is there any good method or methods within our means by which these waters can be improved?

The self-purification of rivers, which was formerly much discussed, we now know is a figment of the imagination, so far as the removal of disease-producing organisms is concerned. For the artificial purification of water a number of schemes have been suggested, and some of them put into quite general practice. Before considering these it should be noted that the improvement desired is the removal of taste, color, odor, dead suspended matter, and microorganisms. The latter is by far the most essential thing, but they are all important. The methods devised for the removal of these objectionable qualities are aëration, sedimentation, and filtration.

The thorough aëration of water, especially when the air is introduced under considerable pressure, is very effectual in removing unpleasant odors and tastes due to gases dissolved in the water. This method of procedure has been strongly advocated by Professor Leeds, of the Stevens Institute, and has been successfully employed in many places in this country. Aëration has been shown to have very little effect in oxidizing the dissolved organic matter, and none at all upon microörganisms.

Sedimentation is of very great value in removing not only the suspended mineral matter, but in getting rid of bacteria as well. For the purpose of freeing water from silt, clay, etc., subsiding reservoirs are in common use, and are often very successful. For the separation of living microörganisms such reservoirs would have to be very extensive, and I do not know that any have ever been built expressly for that purpose.

Filtration is the means that has most commonly been recommended to free water from disease-producing bacteria. As this method removes not only living organisms, but also all suspended matter, more or less of the color, and as it oxidizes a considerable part of the disorganized organic matter, it is the most efficient means of purification with which we are acquainted. There is no doubt that filtration can be relied upon to remove from 95 to 99 per cent. of the bacteria contained in the water applied to the filter, and that this will practically free the water from disease-producing qualities. It has been argued by some, even among the medical profession, that because bacteria are living structures capable of indefinite reproduction, the passage of any through the filter would render the filtration useless; and this would be so if water were like milk or bouillon, a favorable culture-medium for pathogenic microbes. But water is far from that, because instead of furnishing a suitable pabulum, our ordinary surface-waters are inimical to the life of the bacilli of typhoid and cholera. The Massachusetts State Board of Health has shown that typhoid bacilli die in the water of the Merrimac River in about three weeks, and most of them in far shorter time, and under the conditions that prevail in distributing mains all forms of bacteria tend to perish quite rapidly.

When by filtration both suspended matter and dissolved organic matter are largely removed, the water is still more unfavorable for pathogenic organisms, and the few that pass the filter do not live to reach the consumer. These theoretic considerations, as they might be thought by some, are entirely confirmed by the results of practical experience in the filtration of water known to be polluted, and its subsequent supply to a large number of people. The now well-known history of cholera in Hamburg and Altona is, perhaps, the most striking illustration of the value of good filtration. There is not the slightest reason to doubt that Altona would have been devastated far worse than Hamburg if it had not been for her filters. For many years Altona, with its filtered Elbe water, has suffered from typhoid fever far less than Hamburg, for which the water was taken directly from the river. In Berlin, too, the water supplied to the city from the Spree is constantly contaminated with typhoid excreta; but, except when overworked, as they are at times, the filter-beds have kept the death-rate from typhoid fever much lower than it is in Paris, Chicago, and Philadelphia. Typhoid fever has long been a phenomenally infrequent disease in London, and this is believed to be due to the filtration practised by all the water-companies that draw from the Thames and Lea rivers, which are always contaminated by sewage. It has, however, recently been determined that the purification of the London waters is due largely to sedimentation in the storage-reservoirs that are possessed by the different companies. Filtration is not managed as carefully as it should be in London, but the combined processes of sedimentation and filtration are successful in removing from 96 to 98 per cent. of the bacteria present in the river water. The diminution of typhoid fever in Lawrence, Massachusetts, since the filter was put in operation, somewhat more than a year ago, is cited as perhaps the only instance of the practical application in this country of sand-filtration to the removal of disease-germs from a public water-supply. There seems to be no question in the minds of those who have investigated the subject that sand-filtration is capable, when properly managed, of rendering perfectly safe a water that is even very seriously contaminated by specific organisms. But the construction and maintenance of a sand-filter is not so simple a matter as was at one time supposed. The careful investigations of Piefke at Berlin, of Kummel at Altona, and of the State Board of Health of Massachusetts, have determined some of the conditions necessary to success. Thus the rate of filtration should never exceed 2,860,000 gallons per acre per day. The rate in Berlin is 1,716,000 gallons, in Altona 1,859,000 gallons, and in seventeen German cities the average is 2,000,000 gallons. The area of the beds is of course determined by the rate of filtration, but there must be a reserve to allow for the beds thrown out of use for cleaning, repairs, etc.

The reserve recommended by most European engineers is equal to one-third of the area in use. In London the total area of the beds is 0.67 acres for each million gallons filtered daily.

The depth of sand in most Continental filters is about two feet, and this has been found to be as effectual as a greater depth, but owing to the somewhat different contents of our American rivers it has been found in Lawrence that the deeper the sand, up to four or five feet, the better. The pressure of water upon the filter should not be excessive, but the depth of water should be enough to prevent heating in summer and to float the ice off the sand in winter. About four feet constitute a good depth. The flow of water should be regulated automatically, and the filters should also be under skilled observation continually. Daily bacteriologic examinations should be made of the applied and affluent water. The greatest care must be taken in cleaning, which must be done every three or four weeks. The surface of the sand must be disturbed as little as possible, and it must never be allowed to freeze. The efficiency of a sand-filter depends upon a layer of silt and organic slime on the surface of the sand. In order that this layer may be maintained in a state of efficiency very great care and attention to details are required.

Of late years there have been largely employed so-called "mechanical" filters, which make use of a layer of ferric hydroxid or alumina upon the surface of the sand, instead of the "dirt layer," as the Germans call the surface of an ordinary sand-filter. In consideration of the difficulties in the management of sand-filters the City Council of Providence voted to construct a system of these mechanical filters—with this proviso, that it should be approved by the City Engineer, the Commissioner of Public Works, and the Superintendent of Health. After experimenting nearly a year the commission unanimously recommended the construction of such a filter-plant; but, owing to legal difficulties concerning patents alleged to cover the process, the works have not been built. The filter on which our experimental work was done was of the Morrison-Jewell type, and was thirty inches in diameter. It contained a bed of crushed quartz, three feet in depth. The filter was washed by running a reversed current of water through the quartz and at the same time agitating it by mechanical means. Various substances were used to produce the artificial filtering layer on the surface, but commercial aluminum sulphate was found to be the best. One-half grain of this to each gallon of water was sufficient to keep the filter working properly. The calcium carbonate in the water was found to be far more than enough to decompose this, precipitating the aluminum hydroxid upon the sand. Very delicate tests were applied several times each day to the effluent to determine if any of the unchanged sulphate passed through; but it could not be detected, even when the amount added was far greater than that found necessary. A minute portion of the hydroxid in suspension does pass through, but experiments in cities that employ this process show that it is all precipitated in the mains or intervening basins, and no test-reaction can be obtained from water at the taps in the distribution. It is certain that if used in the proper amount, and indeed far in excess of that, none of the aluminum in any form would reach the consumer. It has been thought by some that even the application of such a small amount of aluminum sulphate as one-half a grain per gallon must be harmful; but if the foregoing is correct, and it was substantiated by hundreds of tests, it cannot possibly exert any injurious action. Indeed, if the aluminum all went through the filter it would probably do no harm, for one-half grain of the commercial sulphate will yield only 0.12 grain of the hydroxid, and far more aluminum than that is contained in many, if not most, spring and well waters. I have made careful inquiry at Lakewood and Long Branch, Chattanooga, Atlanta, Newport, and a number of other cities which have used the "alum process," as it is sometimes called, and have failed to elicit any information which would show that the addition of "alum" to the water was unwholesome.

Our experiments showed that the filter was easily managed, and, for removing bacteria as well as for the other purposes of a filter, was more efficient than any other practical method with which we were acquainted. Our bacteriologic tests were made with great care, and for a large number of days hourly samples were taken. The average removal of water-bacteria as given by these tests was 98.7 per cent. Of course, the most satisfactory test of a filter is not the removal of water-bacteria, but the removal of pathogenic forms applied in known amount. We were so situated that it would have been imprudent to use typhoid bacilli, but instead we employed *B. prodigiosus*, which reacts in water much the same as the typhoid bacillus, and is largely used by the Massachusetts State Board of Health in their filter-experiments. The average removal of this organism was 99.8 per cent.

The removal of coloring matter amounted to about 80 per cent. The removal of the "free ammonia" was often complete, and of the "albuminoid ammonia"—dissolved organic matter—was 66 per cent. This is important, as it is much better than can be done with a sand-filter, and the removal of this material by precipitation removed just so much of the pabulum of the microörganisms.

It is very likely that for some cities sand-filters are to be preferred, for when properly managed they do excellent work. But I believe that the best results are more likely to be obtained by the "mechanical" plan, and I therefore urged its adoption by my own city.

CLINICAL MEMORANDA.

A REVIEW OF SIX INTERESTING PATHOLOGIC CASES.

BY E. R. AXTELL, M.D.,
OF DENVER, COL.;
PROFESSOR OF HISTOLOGY AND BACTERIOLOGY, MEDICAL DEPARTMENT OF THE UNIVERSITY OF DENVER, PATHOLOGIST TO THE ARAPAHOE COUNTY AND ST. LUKE'S HOSPITALS.

CASE I. *Miliary tuberculosis; hemorrhage in the brain.*—Jesus V., forty-eight years of age, a Mexican, was admitted to the Arapahoe County Hospital, February 7, 1894, with a history of chronic illness and cough, with recent retraction of the head and delirium. He came under the care of Drs. McLauthlin and Eskridge, who after an extended examination diagnosticated meningeal tuberculosis. Deep coma came on, and on the 10th of February the patient died.

The post-mortem examination revealed the following condition: The patient's body was greatly emaciated. The membranes of the brain were exceedingly anemic. There was a milky-white exudate under the arachnoid, over both cerebral convexities, over the cerebellum on both upper and lower surfaces, along the anterior and middle cerebral arteries, in the anterior perforated space, and in the inter-peduncular space. Over the anterior surface of the pons, near the basilar artery and around the medulla, there were numerous tubercles imbedded in the inflammatory lymph and in the pia covering these structures.

In the left cerebral hemisphere, involving the medial surface and the upper portion of the convex surface of the hemisphere, there was a dark tumor-like mass lying in the quadrate lobe. Its anterior border was just in front of the upper portion of the fissure of Rolando, and the posterior border was at the parieto-occipital fissure. Laterally it extended from the median line outward one inch. Below it did not extend to the lateral ventricle. For a distance of from one-eighth to one-fourth of an inch surrounding the mass on its outer side was a layer of yellow softening. The tumor-mass resembled extravasated blood, with some appearances of a vascular infiltrating glioma. The remainder of the brain-substance was apparently normal. Sections of the hardened tumor-like mass were made, and it proved to be a simple extravasation of blood, due to a cerebral apoplexy.

The left pleura was free, except for some strong adhesions at the apex. The left lung presented a great many disseminated areas of tuberculous consolidation. These were of all sizes and of all shapes. The apex was solid for two inches down. The right pleura presented strong and old adhesions throughout. The upper half of the right upper lobe was completely solidified, and two small cavities were present at the extreme tip, each about three-quarters of an inch in diameter. Many small areas of consolidation existed in the middle and lower lobes of this lung. All presented tubercles. The heart was small, but its muscular tissue was normal in consistency, and the valves were normal. On the inner surface of the aorta there were a number of small calcareous plaques.

The abdominal cavity presented the point of greatest interest. Over the intestines and stomach, over the liver, over the diaphragm, over the spleen, pancreas, and bladder, indeed, following accurately every curve of the peritoneum, there was a grayish-white exudate from one-twentieth to one-sixteenth of an inch in thickness, and which could be peeled off without much difficulty, and in which were imbedded "millions" of miliary tubercles. The appearance as presented to the naked eye was as though a thin pliable layer of rough undressed kid or molded paper-pulp covered the peritoneum. Here and there the intestines were matted together by friable, easily broken down, fibrinous bands. In one square inch of the exudate I counted on its surface a hundred and eight tubercles. If we estimate the surface-area of the peritoneum at ten square feet the number of tubercles in this man's abdomen was 155,520.

In the dependent parts of the abdominal cavity there were three or four ounces of clear serous fluid. Section of the liver, spleen, and pancreas showed these glands to be normal, and no tubercles were found within. The left kidney was normal. The right kidney was likewise normal, except a few small cheesy areas in the cortex, none larger than a grain of wheat. The supra-renals were normal. The spinal cord was not removed.

From the wide distribution of the tubercles in this case it certainly falls under the head of miliary tuberculosis.

CASE II. *Acute croupous pneumonia; empyema; universal pericarditis; myocarditis and aortic aneurysm.*—J. J. G., an American, forty-seven years of age, was at the time of his death under the care of Dr. S. A. Fisk, who, six months before, had diagnosticated an effusion in the left pleura, with probably some tuberculosis of the left lung, and who had had a large amount of serous fluid aspirated at that time. The trouble continuing, empyema was suspected. A sudden onset of inflammatory symptoms occurred just before death, and an acute inflammation of the left lung was diagnosticated. A few days before his death the man spat up some blood, and an hour before he died he remarked that he felt inside his chest as if his blood was pouring out. In the left pleura was found a quart of sero-purulent fluid. Between the upper and lower lobes of the left lung much fresh inflammatory lymph was found. The entire left lung, from apex to base, was found in a state of red hepatization of acute croupous pneumonia. In the lung there were no tubercles and no cavity. The right lung was large, distended, emphysematous, and full of blood. Otherwise it was normal. The pleura was free. The pericardium presented universal adhesions. The cavity was completely obliterated. The adhesions were old, but they gave way to force. The heart-wall was friable and presented a deep reddish-purple color, with some mottling here and there by yellow patches. The endocardium presented large areas of racemose reddening. All of the heart-valves were normal.

From the aorta, just as it was given off from the left ventricle, there arose an aneurysm the size of a big fist, which projected to the left and anteriorly. This was filled with a mass of dark, grumous blood and partly and completely organized clots. The aneurysm had no opening into adjacent structures. The blood which had been spit up came no doubt from the distended vessels of the right lung.

The spleen and pancreas were normal. Both kidneys were large and congested. The liver was deeply congested. The intestines and stomach were normal. The brain and spinal cord were not examined.

The case from a pathologic point of view was certainly a very interesting one. I felt sure that if we had been allowed to examine the brain we would have found a thrombosis. The sudden and rather unexpected death might have been due to true heart-failure, but from the condition of the clot in the aneurysm it is very probable that an embolus was the factor which immediately caused death. What occurred when the man felt his blood pouring out in his chest can only be surmised. As the clot in the aneurysm was very loose when it was examined, it is possible that its separation was occurring when he uttered his cry.

CASE III. *Subacute interstitial nephritis plus an acute parenchymatous and interstitial inflammation, probably "ether-nephritis."*—Charlotte C., thirty-five years of age, unmarried, was admitted to the Arapahoe County Hospital, March 27, 1894, under the care of Drs. McLauthlin and Collins. The history obtained was as follows: Five years ago she began running down, having malaise, frontal headache, leukorrhea, and many uterine reflexes. This condition continued up to her admission into the hospital. Up to six months ago menstruation was regular, but since that time she has menstruated much oftener than she should. On admission, her temperature under the tongue was 96° F., but on the following day it was normal, and it continued so for five days. The urine was carefully examined. Its specific gravity was low, and the amount passed was large, but it contained no albumin. A microscopic examination was not made.

On the sixth day after admission the woman had a temperature of 100°. After consultation and repeated examinations the trouble was diagnosticated as a pus-tube, and celiotomy was advised. The patient had been under Dr. Collins' care before for a partly adherent retroverted uterus.

On April 5th Dr. Collins performed celiotomy, and removed both tubes and ovaries. The left tube contained pus, and the right ovary was badly cystic. After the operation the temperature rose to 102°, then to 104°, and on the day of death to 106.8°. No symptoms of peritonitis were present at any time. The woman went into a state of coma, and died while in that state six days after the operation.

What had caused the patient's death was the question given me to solve. The post-mortem examination showed the following conditions: The abdomen was distended; there was an incision in the median line, below the umbilicus, for a distance of five inches. This cut showed nothing purulent. It had begun to heal throughout. The peritoneum below the cut was a little dark in color, but there was nowhere any evidence of peritonitis. The intestines were distended and projected from the abdominal cavity for about six inches. In the dependent portions of the abdominal cavity there were a few ounces of blood-stained serum. The peritoneum over the uterus, and all through the pelvic basin, was very dark in appearance, a grayish-black, and it was apparently disintegrating. It brushed oft readily under the finger. There was an area the size of a watch on the ileum at the ileo-cecal valve, which was very dark and apparently necrotic, but this was all in the peritoneum, for section showed nothing else to be involved. The uterus was normal and movable. The stumps of the tubes were in good condition. Not a drop of pus, not a thread of fibrin, not an adhesion was found anywhere. The intestines were normal, although distended, and nowhere showed any peritonitis. The stomach was normal except in one or two places where the superficial epithelium was cast off, and where it looked as though there might have been ulcers at one time. The spleen was only one-fourth the normal size. The liver, pancreas, and suprarenals were normal. The left lung and pleura were normal. The right lung showed some catarrhal pneumonia, and much hypostatic congestion in the lower lobe. The pneumonia was principally located at the edges at the base and posteriorly. The pleura of this lung was normal. The pericardium was normal. The heart was small, and showed some fatty deposit over its anterior surface. The endocardium was normal except for slight evidence of inflammation of the mitral valves.

The right kidney showed the medullary portion quite deep in color. Its cortex measured about one-fourth of an inch, and was quite tough on section. The capsule was thickened, and on removal a portion of the cortex was torn away with it. The Malpighian bodies were not distinctly made out, and the tissue of the cortex could be seen to be more firm, dense, and translucent than normal. Section of this kidney showed that in addition to the interstitial process, with some chronic changes in the tubules and tufts, there was an acute inflammation present not only in the epithelial lining of the tubules, as seen by extensive desquamation and casts, but around and about the tubules, where a large array of leukocytes was found in the thickened connective tissue. The left kidney presented but few naked-eye appearances of any trouble, and on section showed nothing marked but cloudy swelling.

The brain and cord were not examined.

Here was a patient who, with an interstitial inflammation of one kidney, was given ether to narcosis for an extensive operation. Her death follows in six days, and an acute inflammation is found in the diseased organ, with no other organ showing extensive trouble.

CASE IV. *Appendicitis; cured tuberculosis.*—John R., a German, twenty-eight years of age, was treated at Davos, Switzerland, by Dr. Carl Ruedi for pulmonary tuberculosis with a great many hemorrhages. Dr. Ruedi said that the blood came from the left lung, and that at the time, five years ago, he could detect no cavity. The man came to Colorado three years ago, and resided at Salida. While under the care of Dr. Maxwell he developed appendicitis, and had had four attacks previous to this one. He refused operation. Five days before his death he developed the attack which was the cause of his death. Dr. Parkhill operated on him, June 7, 1894, and found the appendix perforated and the abdominal cavity partly filled with pus and lymph. The appendix was removed and the abdominal cavity washed out. The man developed septicemia, and died June 9, 1894.

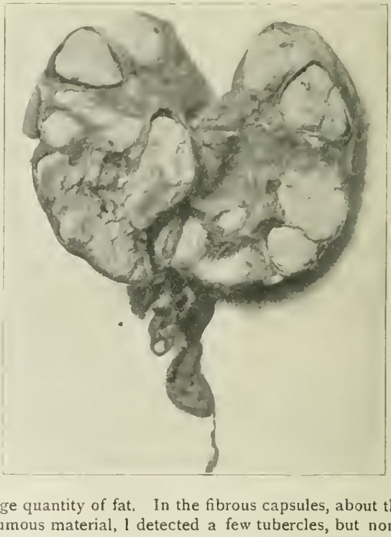
All of the intestines were distended, and lymph and sero-pus were in all the folds of the intestines, even up to the spleen. The omentum was bound down to the pelvic brim on both sides. The stump of the appendix was low down and lay very posteriorly. It was about three-fourths of an inch in length and was in a very softened, semi-gangrenous condition. Old adhesions existed about the colon, evidences of previous inflammations. The spleen was small and cirrhotic; the other abdominal organs were normal, as were the kidneys. The heart was normal. The left lung presented old adhesions at the apex and at the tip of the lower lobe, at which point there was a well-marked, clearly-outlined tuberculous cavity an inch and a quarter in diameter, beautifully isolated and separated from the rest of the lung by a dense fibrous capsule fully a twelfth of an inch thick. It was almost empty, but contained a small amount of cheesy tuberculous material. It was traversed by two or three tiny fibrous bands, and had two or three bronchi opening into it on its inner surface. It showed a few tubercles. The rest of the lung was normal. There was not a single infiltrated area anywhere, and not a tubercle could be found. The right lung was normal throughout. The right pleura presented a few adhesions at the apex and at the base posteriorly. The brain and cord were not examined. Certainly we had here a case in which Nature, aided by our generous climate, had isolated, and had in her own way practically cured a genuine tuberculosis. The bronchi opening into the cavity were large and were so situated as to drain.

CASE V. *Chronic hemorrhagic nephritis; nephrophthisis.*—Robert C., a laborer, forty years of age, born in Denmark, was admitted to the County Hospital, June 13, 1894, in a delirous condition. No history was obtainable, but Dr. Henry Sewall found many bubbling râles in the chest, indicative of pulmonary edema. The pulse ranged from 120 to 128, the temperature from 99.5° to 102°, and the respirations from 36 to 64. A careful examination of the urine showed a small per cent. of albumin. The patient continued delirious and had to be tied down in bed. Treatment directed toward the kidneys failed to produce any results; the patient became comatose, and died June 15th.

Dr. Mack, the hospital resident, stated that the patient had been in the hospital a year before for a supposed tuberculous testicle, which was removed.

The post-mortem was made seven hours after death. The left pleura had a few slender, old adhesions at the apex of the lung. The right pleura was adherent everywhere, but the bands could be broken down with the hands, except at the apex, where they had to be cut. The left lung was greatly edematous, and on section a part in the lower lobe looked as though it was in a state of catarrhal pneumonia, but the part floated on water and presented no elevated and depressed patches, and was, no doubt, simply edematous. The right lung was in the same state as the left, except that at the apex the pleura was thickened for a quarter of an inch. The bronchi in both lungs were filled with edematous fluid, which was blood-stained and frothy. The pericardium was normal. The heart was more than one-half again the usual size. The wall of the left ventricle was greatly hypertrophied, being fully five-sixths of an inch thick. The aortic valves and the aorta were normal. A large white clot was present in the left ventricle and in the aorta. The left heart was found strongly contracted. The mitral and pulmonary valves were normal. The right ventricle was dilated and its walls were thinned for such a large heart. A large, firm, white clot was present in this ventricle. The spleen was normal.

The left kidney was "a revelation." The organ was four inches long, two inches wide, and was buried in a mass of fat. The surface was found raised in rounded elevations the size of a large marble. The color externally was dark and bluish. On section the knife was covered with a white grumous paste, and the same material bulged from the kidney. The capsule of this organ was thickened to one-twelfth of an inch, and could not be removed. Running from the capsule into the kidney were a few thick fibrous bands like the capsule. Every vestige of a renal cortex and medulla had disappeared, being broken down into the whitish-gray, grumous material mentioned. This material was soft, like soft cheese. It could be spread, and would not dissolve in potash or chloroform. It lay in well-formed, fibrous capsules from which it could be easily removed, leaving cosy nests. The fibrous walls about were rather smooth, and, unlike what I expected to find, were not markedly ulcerated. A large mass of the cheesy material occupied the pelvis of the kidney and the beginning of the ureter. The mucous membrane of the pelvis seemed to be normal, though anemic. About the pelvis was a large quantity of fat. In the fibrous capsules, about the grumous material, I detected a few tubercles, but none was present in the capsule of the kidney or in the pelvis. There was no suppuration. Dr. Le Garde examined the cheesy matter for the bacillus of tubercle, but found none. He pronounced the material to be granular débris and fat. He also examined the septa for the bacillus of tubercle, but he found none. From the distinctive naked-eye appearances of the kidney, however, I pronounced it tuberculous. The cheesy mass found was no doubt due to a tuberculous process, probably sec-



ondary to the tuberculous testicle, or possibly had been itself primary. The ureter and bladder were normal, although this examination, I regret to say, was hastily and carelessly made.

The accompanying illustration shows the destruction of the kidney-tissue.

The right kidney was four and a half inches long by two and a half inches wide. The cortex and medulla were separate and fairly distinct. Both the cortex under the capsule and the cortex on section, as well as the medulla, were mottled with white. The section presented light red areas alternating with lighter gray or yellowish-gray areas. The cortex was a little thickened, and a few small hemorrhages were present. The capsule stripped nicely. The pelvis was normal. To the naked eye this kidney presented all of the appearances of chronic hemorrhagic nephritis. The gray or yellow parts corresponded to the anemic or fatty-degenerated portions. Dr. Le Garde reported that the sections revealed parenchymatous and fatty degeneration of the epithelium lining the tubules, with granular infiltration of the interstitial tissue; thickening of the capsule of some of the glomeruli, and complete destruction in places of the uriniferous tubules.

Both supra-renals were cystic. The glands were apparently normal in size, but the parenchyma was lacking, and only a small bit of a semi-fluid brownish material occupied its center. A long observation of the supra-renal glands convinces me that they are often cystic, and that they break down quickly after death, if indeed not before.

The liver, pancreas, stomach, and intestines were normal. The brain and cord were not removed.

The specially interesting pathologic feature in this case was in the left kidney. It was the form of kidney called by the old authorities "scrofulous disease of the kidney," "strumous pyelitis," "scrofulous pyelo-nephritis," and the "inflammatory form of tuberculous disease of the kidney." In reference to the formation of the cheesy material found in it, Morris (in the *International Enclycopedia of Surgery*, vol. v, page 676) says: "Whether these cheesy masses are due to retrograde changes in confluent groups of miliary tubercles, or are the results of degeneration of the products of ordinary inflammation, pathologists are not agreed; some, indeed think that both conditions may exist at once, but that under such circumstances the tubercular process takes precedence of and excites the inflammatory changes." Such being the truth the absence of the tubercle-bacillus need not invalidate our diagnosis.

Case VI. *Chronic parenchymatous nephritis, the inflammatory fatty kidney.*—Thomas W., a laborer, sixty years of age, born in Ireland, was admitted to the County Hospital, June 9, 1894, under the care of Dr. W. J. Rothwell. He had had malaria and dysentery. He was in perfect health in June, 1893, when, while walking on an elevated railroad track in New Mexico, he fell and injured his left leg. He was severely tumbled, and suffered from profound shock. He was taken to a Union Pacific Railroad Hospital, and was there for three months, being delirious much of the time. After he left the hospital he did a little work, but was not strong or well. He progressively ran down in health and became anemic and felt poorly. He came to Denver, and was sent out to the Arapahoe County Poor Farm. Here he began to have occipital headaches and diarrhea.

When the patient was admitted to the hospital he was intensely anemic, and his blood showed a deficiency of hemoglobin. The examination of the urine by the house-interne revealed nothing abnormal. This examination I believe to have been carelessly made.

The diagnosis was thought to lie between carcinoma and pernicious anemia.

On June 18th the patient vomited something that might be called "coffee-ground vomit." Mental apathy then came on, and he died in stupor June 20th. The night before he died the temperature in the axilla was 95°.

The post-mortem examination was made forty hours after death. The right pleura was free of adhesions. The lung floated in a pint and a half of blood-stained serum. The pericardium was normal and contained an ounce of clear serum. The heart was enlarged a third. It was very flabby and had much subserous fat on its anterior surface. All of the heart-valves were normal. Both of the heart-ventricles were dilated. The walls of the heart were friable and thin. The lungs were normal, but exceedingly edematous. Many old adhesions were found over the spleen. This organ was enlarged a half. It was very soft and friable. The left kidney was movable, forward, up to the median line. It lay imbedded in a mass of fat, and was enlarged about a third. It was pale and light in color and the capsule stripped, leaving the outer surface smooth and of a gray-yellowish red color, the yellow being pronounced here and there. The cortex was half an inch thick and showed a yellow faint mottled appearance. The pyramids were more prominent than usual, the red vessels and the yellow tubes being strongly contra-distinguished. No hemorrhage of any size could be detected. The pelvis was normal. The yellow of the cortex was very prominent in places. It was arranged in wedge-shaped masses, with the base at the cortex and the apex at the pelvis. It was a beautiful specimen of the inflammatory fatty kidney. I follow Strümpell's classification of chronic nephritis:

1. Chronic hemorrhagic nephritis, the large variegated or mottled kidney.
2. Inflammatory fatty kidney, the large white kidney.
3. The secondarily contracted kidney.

The right kidney was not movable. It was much more nearly normal than the left one, but its upper half was in the same condition as the left. The liver was large and apparently in a condition of cloudy swelling. All of the other abdominal organs were normal. The supra-renals were cystic. The brain and cord were not removed.

This case showed the value of a post-mortem examination. It had been registered "pernicious anemia" at one time.

POST-MORTEM DEMONSTRATION OF A CASE OF PYEMIA, FOLLOWING A LATENT OTITIS MEDIA.

By S. B. CLARK, M.D.,
of Chicago.

The case reported occurred in a post-mortem examination at the Cook County Morgue, under Dr. Ludwig Hektoen, October 18, 1893. The patient was a man, aged twenty-one, a porter by occupation; of negative family history. He was admitted into the hospital October 21, having been sick about three weeks; he complained of chills, fever, nose-bleed, loss of appetite, and general debility; no cause was given for the sickness, and the man had previously been well. When admitted he was stupid, the skin yellowish, the tongue thick and coated; examination of the lungs and heart was negative; the spleen was not enlarged. The temperature was about normal and the pulse slightly accelerated. On the second day after admittance he had a marked chill, and the temperature rose from 97.5° to 102°. Chills and fever continued in such irregular manner that malaria was suspected, but blood-examination was negative. The pulse was generally over 100, and when the chills came on would rise as high as 140 or more.

On October 8th tenderness and pain developed in the right lung over the region of the mammary gland; there was dulness on percussion, and the respiratory and vocal sounds were somewhat diminished. On October 18th, the apex-beat of the heart was displaced to the left of the nipple-line one inch, in the fifth interspace, and cardiac dulness was increased. The pulse became rapid and jerky, and the patient died in an exhausted condition.

The post-mortem examination revealed the following changes: The body was much emaciated; examination of the abdominal contents was negative, except that there was swelling of the mesenteric glands. The pericardium, with the heart, was compressed and pushed toward the left side by turbid semi-solid fluid in the right pleura, held in by adhesions. The pericardium was also adherent to the left lobe, and in front the pleura was adherent to the sternum by grayish purulent masses. An opening was seen through the left pleura back of the sternum, that communicated with the lung.

In the left pleural cavity were weak adhesions, and a small quantity of turbid, yellowish fluid, in which were solid fibrinous masses. The heart-examination itself was negative.

The right lung showed numerous septic infarcts anteriorly where the pain had been felt. The lobes were adherent, and many yellowish softened areas, with their bases toward the pleura, were easily discernible, of a foul odor, and some of them fused together, containing purulent material. This lung did not float, and when incised showed many yellowish necrotic foci.

The original cause of these many metastatic foci could not yet be accounted for, and we made preparations to examine the brain.

In the meantime the right internal jugular vein, from its commencement at the jugular foramen to the right innominate vein, was found to be in a condition of suppurative thrombo-phlebitis, and contained a semi-solid mass of foul, viscid, purulent material from begining to end.

After the calvarium was removed and the brain taken out, a septic focus was found in the middle ear, and another in the mastoid cells, and leading from this the veins connecting with the lateral sinus were found in a condition similar to the internal jugular.

The lateral and other sinuses of the dura mater were in a suppurative, thrombo-phlebitic condition also.

This readily explained the route of infection, down the lateral sinus to the internal jugular vein, thence through the innominate vein, the superior vena cava, and heart to the lungs.

The autopsy well illustrated how a trifling little abscess of the middle ear, so small as not to be noticed by the patient, may cause the gravest form of pyemia and death.

MEDICAL PROGRESS.

Bilateral Orchectomy for Chronic Hypertrophy of the Prostate.—At a recent meeting of the Allegheny County Medical Society, at Pittsburg, DR. J. D. THOMAS reported the case of a man, sixty years old, who for ten years had had progressively increasing frequency of micturition, so that in urinatiing he was compelled to get upon his hands and knees, thus emptying his bladder by drops. The straining resulted in prolapse of the rectum. A catheter had been used, but the pain was so intense that the practice was abandoned. The urine was neutral in reaction, and contained a large amount of pus. There were two ounces of residual urine. A soft catheter could be introduced without much difficulty, and on rectal examination both lobes of the prostate were found to be considerably and uniformly enlarged. Bilateral orchectomy was proposed, accepted, and performed. Improvement in urination was perceptible within a few days, and continued subsequently without medicinal treatment. The urine could be retained for from two to six hours by day and for two hours at night. Micturition was attended with little pain. On rectal examination the size of the prostate gland was found to have appreciably diminished.

A Mindless Frog.—At a recent meeting of the Association of American Anatomists in New York, PROF. BURT G. WILDER showed a frog from which, under ether, the entire cerebrum had been removed three weeks before. The animal looked natural. The scar on the head was hardly visible. The frog could swim and jump and even balance on a cylinder slowly turned, and could swallow food placed far back in the throat. When undisturbed it sat without motion, and presumably had no consciousness. That such a frog, while in possession of all its senses (excepting smell, the olfactory lobes being removed with the cerebrum), had no intelligence was shown by the behavior of a similar specimen shown the American Neurological Association in 1886. A minnow was put into the mouth. The head reached the throat and aroused the swallowing reflex; but the tail protruded from the lips and caused the frog to put up its hands to push it out. The normal frog would have decided whether the fish should go up or down. The decerebrized animal was a mere reflex machine, and could make no choice between incompatible operations.

A Case of Muscular Dystrophy.—At a recent meeting of the New York Neurological Society, SACHS presented a young woman with all the characteristic symptoms of muscular dystrophy of the facio-scapulo-humeral type. On attempting to show the teeth she was able to move the lower lip slightly, the upper one not at all. There was also loss of power in the eyelids, and the symptoms in the region of the shoulder-girdle were very characteristic. There was distinct hypertrophy of the infra-spinatus and supra-spinatus, and atrophy or partial atrophy of the serratus, the pectorals and the rhomboids. The patient was unable to raise her arm beyond a horizontal position. In excising quite a large piece of the infra-spinatus muscle, a considerable part of the nerve, as it enters the muscle, was accidentally removed. Histologic examination disclosed a great preponderance of fatty tissue, with hypertrophy of some and atrophy of most of the muscular fibers, and distinct evidence of degeneration of the nerve. Decided improvement in the condition of the patient took place. The muscles of the lower extremities were slightly atrophied.

The Protective Influence of the Blood-serum of Convalescents from Diphtheria and of Healthy Individuals.—As the result of an experimental investigation, ABEL (*Deutsche medicin. Wochenschr.*, 1894, Nos. 49, 51) arrives at the conclusion that the blood-serum of many healthy individuals, between the ages of twenty and forty years, who have never had diphtheria, possesses the property of protecting guinea-pigs against infection with diphtheria. It was found that the blood-serum of convalescents from diphtheria did not possess a similar property for the first few days after the cessation of the disease (disappearance of the membrane), but that this property manifested itself in the majority of cases after the lapse of from eight to eleven days, disappearing again at the end of several months, but not in all cases.

The Presystolic Murmur.—At a recent meeting of the Société de Biologie BERNHEIM (*La Médecine Moderne*, 1894, No. 89, p. 1386) contended that the so-called presystolic murmur is in reality systolic, as sphymographic tracings show that a tenth of a second elapses between the systole and the occurrence of the murmur. The murmur also follows the impulse of the heart.

To Stain Nervous Tissue AZOULAY (*Bulletin de la Société Anatomique de Paris*, October, 1894, p. 676) immerses for fifteen minutes sections impregnated with osmic acid in a 10 per cent. solution of tannic acid. The myelin is thus colored black, and the sections may be subsequently stained with carmin.

Sporozoa in Sarcoma.—VEDELER (*Centralblatt für Bakteriologie und Parasitenkunde*, Band xvi, No. 21, p. 849) describes a sporozoon which he found in sections of sarcomata, and which he believes to be the specific cause of these neoplasms.

THERAPEUTIC NOTES.

The Treatment of Diphtheria with the Antitoxin.—Of twenty-four cases of diphtheria treated with the antitoxin by KUNTZEN (*Deutsche medicin. Wochenschr.*, 1894, No. 49, p. 918), recovery ensued in 21 and death in 3. Two cases that came under observation on the first day, 6 that came under observation on the second day, 2 that came under observation on the fourth day, 2 that came under observation on the fifth day, and 1 that came under observation on the eighth day of the disease, recovered. Of 7 cases that came under observation on the third day, 6 recovered and 1 died; 1 that came under observation on the sixth day died; and of 3 that came under observation on the seventh day, 2 recovered and 1 died. Tracheotomy was necessary in 5 cases, 2 of which were fatal. The diagnosis was in all cases based solely on clinical data.

SONNENBURG (*Deutsche medicin. Wochenschr.*, 1894, No. 50, p. 930) reports that from June, 1893, to October, 1894, Behring's antitoxin was employed at the Moabit Hospital in Berlin in the treatment of diphtheria, with two intermissions when the serum was not attainable. These intervals occurred from July 1, 1893, to December 1, 1893, and from April 1 to July 31, 1894. The injections were given immediately after admission, from 600 to 1800 immunity-units being administered, according to the severity of the case. During the period of serum-injections 107 cases were treated, with 85 recoveries (79.4 per cent.); tracheotomy was required in 34, of which 26 recovered (76.5 per cent.); 12 cases were not injected from economic reasons; of these, 6 were mild, and recovered; 6 appeared hopeless, and died soon after admission. Of the 95 cases treated with injections 79 recovered (83 per cent.). In the intervals during which no serum was available, 116 cases were treated; of these 84 recovered (72.4 per cent.); 47 required tracheotomy, with 29 recoveries (62 per cent.). Most of the fatal cases treated with the serum came under observation on the third day, or later. Since October, 1894, prophylactic injections of 60 immunity-units have been made among the brothers and sisters of cases of diphtheria. Of 16 cases thus treated dipththeria developed in two, both of which responded readily to injections of 600 immunity-units, and pursued a mild and favorable course. In one of these cases the disease was probably already present at the time of the prophylactic injection. In the other the attack occurred thirty-seven days after the injection.

At a recent meeting of the Berlin Medical Society, HANSEMANN (*Berliner klinische Wochenschrift*, 1894, No. 50, p. 1126) formulated the conclusion that there is no scientific reason, theoretic or experimental, for considering the antitoxin of diphtheria a specific remedy in the treatment of diphtheria in man. It was contended that the demonstration of any specific curative property of the serum in man had not yet been practically made, and it was pointed out that the agent may, under certain circumstances, act injuriously, exercising a destructive influence upon the blood and causing irritation of the kidneys.

In the discussion, VIRCHOW (*Münchener medicin. Wochenschr.*, 1894. No. 50, p. 1023) related that of 533 cases of diphtheria at the Kaiser and Kaiserin Freidrich Kinderkrankenhaus, 303 were treated with the antitoxin, with a mortality of 13.2 per cent., while among 230 treated with other measures the mortality was 47.8 per cent.

At a recent meeting of the Société Médical des Hôpitaux, MOISARD (*Le Mercredi Médical*, 1894, No. 50, p. 613) reported the employment of the antitoxin during the months of October and November, 1894, in 248 cases of diphtheria, with 34 deaths (14.71 per cent.). In 14 cases an urticarious eruption developed; in 9, a scarlatiniform erythema; in 9, erythema multiforme, and in 1 a purpuric condition.

LE GENDRE (*Médecine Moderne*, 1894, No. 100, p. 1678) related that he had employed the antitoxin in the treatment of 16 cases of diphtheria, with 2 deaths.

LEBRETON (*Ibidem*) reported that during October and November there had been treated at the Hôpital des Enfants 242 cases of diphtheria, with 28 deaths (11.66 per cent.). Deducting cases in which death followed within twenty-four hours of coming under observation, the mortality did not exceed 8 per cent.

SEIZ (*Therapeutische Monatshefte*, 1894, H. xii, p. 605) reports that from July 1, 1893, to the middle of October, 1894, there were admitted to the hospital at Constance 159 cases of diphtheria, mostly of severe grade, 66 of which terminated fatally (41.5 per cent.). Tracheotomy was necessary in 54 cases, intubation in 8. In addition, 134 cases occurred in the city, with 24 deaths (17.9 per cent.). Included in these statistics are 27 cases treated with antitoxin, with a single death. Of these, 20 received injections on the first day; 4, on the second; 1, each, on the first and second, and on the first and tenth days. The fatal case came under observation on the third day, with stenosis of the larynx, and died within a short time.

MENDEL (*Berliner klin. Wochenschr.*, 1894, No. 48, p. 1088) has reported the case of a boy, four-and-a-half years old, in which, on the second day of an attack of diphtheria of moderate intensity, one-thousand immunity-units of Behring's antitoxin were injected, and on the third day an additional six-hundred units. On the seventh day, contrary to instructions, the patient arose from bed, and shortly afterward a generalized hemorrhagic exanthem suddenly made its appearance. A particularly large area of hemorrhage occupied the site of injection. There were, besides, pains in the extremities. The condition slowly receded without relapse, and recovery ultimately ensued. The complication is ascribed to the action of the serum, which, it is known, has a destructive effect upon the red blood-corpuscles, and of which 20 c.c. were employed.

Salicylated-Iron Mixture.—

℞.—Sodii salicylatis	ʒiv.
Tinct. ferri chloridi	fʒiv.
Acidi citrici	grs. x.
Glycerini	f℥iss.
Ol. gaultheriæ	♏ viij.
Liq. ammon. citratis, q. s. ad.	f℥iv.♏

Sol. sec. art. dos. fʒj or f℥ij.

Dissolve the citric acid and sodium salicylate in the liquor ammonii citratis. To the glycerin add the tincture of iron chlorid, and then mix the two solutions, finally adding the oil of gaultheria. One or two drams of mucilage of acacia would be a valuable addition with which to emulsify the oil of gaultheria.

In this prescription reaction takes place between the ferric chlorid and sodium salicylate, resulting in double decomposition, giving iron salicylate in the first solution. Care should be taken to keep the liquor ammonii citratis in slight excess, in order to have a perfectly clear solution of salicylate of iron.

Dose.—One or two teaspoonsfuls.

This prescription is used principally in the treatment of chronic cases of rheumatism or rheumatoid arthritis in which anemia or other evidence of impaired nutrition is a distinct feature. It is likewise employed in acute tonsillitis of rheumatic origin, and in acute articular rheumatism in anemic subjects, especially if the patient has suffered from one or more previous attacks.

The ordinary dose in chronic cases in adults is a dessertspoonful four times a day; in acute cases the same dose is given every two hours until tinnitus is produced or decided amelioration has occurred, when the dose is diminished or the intervals between doses lengthened.—S. SOLIS-COHEN, *Phila. Polyclinic*, vol. iii, No. 32, p. 31.

Recovery from the Ingestion of One Ounce of Chloral Hydrate.—At a recent meeting of the Clinical Society of London, COLENSO (*Medical Press and Circular*, No. 2895, p. 454) reported the case of a very powerful woman, thirty-four years old, of large build and good condition, who deliberately took an ounce of chloral hydrate in solution, being discovered in bed unconscious eight hours later. When seen, an hour and a half after this, the patient was found to be comatose. The reflexes were abolished; the breathing was shallow and stertorous; the pupils small and sluggish; the pulse 130, small and firm; the temperature 100.5°. It was only three hours later that the nature of the poison taken was discovered. Atropin was given hypodermically, and the stomach washed out with much difficulty. Strychnin and ether were injected subcutaneously, and amyl nitrite given by inhalation. When the nature of the poison was learned, enemata of strong coffee were given, and sinapisms applied to the thighs and legs. The woman was also vigorously rubbed and slapped with towels. The treatment was thus continued for several hours, the patient finally being roused. Short intermissions of ten minutes at a time were allowed for sleep, then the patient was taken from bed and made to walk about. On the following day the patient slept thirteen and a half hours of the twenty-four. Recovery ultimately ensued.

The Treatment of Pyrexia.—WHITE (*British Medical Journal*, No. 1768, p. 1096) maintains that hyperpyrexia should be energetically treated with cold baths, while the routine use of antipyretics in ordinary pyrexia is to be condemned. In the cases in which benefit follows coincidently with the reduction of the temperature the means employed has a specific beneficial effect on the particular disease; consequently, the temperature falls at the same time as the other symptoms improve. The means used is only antipyretic in the same sense as mercury is antipyretic in syphilitic fever. Phenazone, acetanilid, and phenacetin should rarely be used as antipyretics.

The Treatment of Scleroderma.—The Vienna correspondent of the *Lancet* (1894, No. 3715, p. 1126) quotes BEER as having reported four cases of scleroderma treated successfully by massage continued for a long period. In one case the treatment was persisted in for a year; in another it was pursued for three hours daily for some months. To overcome the muscular atrophy the faradic current proved useful. One of the patients, who weighed only thirty-two pounds when the treatment commenced, and whose muscles were so atrophied that he could not move his extremities, which were held in a flexed position, recovered, and weighed one-hundred-and-five pounds after treatment for some months.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM, IN ADVANCE $4.00
SINGLE COPIES 10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM . . . 7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,

PHILADELPHIA.

SATURDAY, JANUARY 5, 1895.

"HIGHER MEDICAL EDUCATION."

MEDICAL men and all who have studied the problems of medical education, its defects and its needs, will read with interest the little work of DR. WILLIAM PEPPER bearing the above title. Surely no man in this country speaks with more authority on this topic; none has done more in molding latter-day opinion and policy, or in inaugurating and practically aiding important reforms. The addresses which comprise DR. PEPPER'S book were delivered before the medical classes of the University of Pennsylvania on October 1, 1877, and October 2, 1893, the dates respectively of the establishment of the three-year and the four-year course in medicine in that institution; and, though they deal mainly with the problems presented to that school, they apply with equal force to the status of medical education in other centers at the same time, and represent most forcibly the former needs and the later accomplishments in the direction of an ideal system of medical education in America.

The first of these addresses is largely retrospective, reviewing with care the origin of medical teaching on this continent, the high plane on which this was conducted at the outset, and the subsequent falling off from these honorable standards.

The medical school of the University of Pennsylvania, having the distinction of being the oldest medical school on the American continent, was founded in 1765, largely by the efforts of JOHN MORGAN and WILLIAM SHIPPEN, JR., both recently returned from their studies in Edinburgh. The plan of organization was closely modeled after that of the larger European schools, and in particular after Edinburgh. Such candidates only were admitted who had received a collegiate degree or who satisfactorily passed an examination in Latin, mathematics, and natural and experimental philosophy. The course of study led first to the degree of bachelor of medicine when the student had served an apprenticeship to a reputable physician, had attained a knowledge of pharmacy, had attended one complete course of lectures, and had followed the practice of a general hospital for one year. A private followed by a public examination were further requisites. After three years the applicant was granted the degree of doctor when he had written and publicly defended some thesis on a medical subject. It will thus be seen that it was no idle boast of the Trustees that their medical school presented as "liberal and extensive a plan as most reputable European seminaries." In particular, hospital instruction was rendered possible by the inauguration of clinical teaching in the Pennsylvania Hospital in 1760, and in the Philadelphia Almshouse in 1770, and continued an obligatory part of the student's work until 1845.

Unfortunately for medical education, this high plane of excellence cannot be said to have been maintained in subsequent years. The rapid multiplication of schools of indifferent worth and the active competition of these led to a steady lowering of standards until in later years the character of medical education in America was truly deplorable. A comparison of European schools in 1877 with those of our own country illustrates this most forcibly. In the former it will be found the student was required to pursue a regularly graded course of instruction extending over a period of four, five, six, or even seven years; he received personal training in all practical and clinical branches, and he was required to pass an impartial examination by disinterested individuals. It is idle, as DR. PEPPER well observes, to state that the conditions in America did not permit of such advanced and prolonged study, and it was indeed the self-complaisant contemplation of their own excellencies that led men to feel that such a course might produce learned philosophers, but not doctors in any way superior in the setting of a fracture or the contrivance of a potion than those of less rigid education.

What a contrast was presented by the American medical schools! In the first place, no preliminary examination at all was required at matriculation, and the course of study was but two terms of less than five months' duration, with a provision that the student "have attended the practice and been the private pupil of some respectable practitioner," a provision which was notoriously useless and practically inoperative. The course of study was entirely ungraded, so that the new student, without a rudiment of medical knowledge, at once entered upon advanced studies with those about to graduate. Voluntary lengthening of the time of study by the student was therefore scarcely advantageous. Instruction was wholly didactic, saving only the practical work of dissection. Finally, and this perhaps more than anything else led to the pernicious system of medical education, the examinations were conducted and degrees conferred by teachers whose remuneration depended altogether upon the size of the classes.

It was this last grave fault, depending largely on the absence of any supervision by the State and the absence of any system of State examinations, that led to the inordinate number of medical schools and the numerous fraudulent establishments which granted diplomas for small pecuniary considerations, and made the very name of "American Medical Diploma" a reproach in all the world. The number of regularly chartered medical schools was and remains to this day ridiculously large, while the number of "bogus" universities and the extent of their operations can scarcely be determined. Of the regular medical schools following the establishment of that of Pennsylvania in 1765, that of Harvard in 1782, and of Dartmouth in 1797, there were established in the succeeding decades respectively, four, six, three, ten, ten and eight, exclusive of various irregular schools. There were thus in operation at the close of the late Civil War forty-four regular medical schools. In the reactionary period following the war, from 1867 to 1877 inclusive, twenty-one medical schools were organized. At the period of Dr. Pepper's first address there were therefore sixty-five regular schools, and in addition eleven homeopathic, four eclectic and fourteen schools of pharmacy. As druggists largely practised medicine, there were practically ninety-four schools graduating practitioners of medicine, or one to 477,392 inhabitants, whereas in the countries of Europe and generally throughout the world one medical school for about 2,000,000 inhabitants has been found the proper proportion. There were graduated in the year 1876 from the American schools about 3000, or from five to six times the number graduated in Germany, or in Austro-Hungary; four times as many as in France, and almost twice as many as in Great Britain. This inordinate over-production had of course led to an undue proportion of practising physicians to the total population; so that while in all other countries there was one physician to from 1800 to 7000 or even 10,000 inhabitants, in the United States there was one to 600 of population. These evils, with the auxiliary and dependent misfortunes, such as unnecessary multiplication of free dispensaries, the stimulation to quackery in consequence of the lowered standards, and the like, are clearly and eloquently set forth; and with rare foresight (looking at the question from the vantage ground of to-day's accomplished events) Dr. Pepper formulated the lines on which reform must proceed.

These reforms were: The establishment of a preparatory examination; the lengthening of the course to at least three full years; the careful grading of the course; practical instruction at the bedside and in laboratories; and the establishment of fixed salaries for the professors, so that they might no longer have any financial interest in the size of their classes. Clearly as these reforms seem to us to-day desirable and sufficient, only those who have had an interest or a part in the accomplishment of the improvements can adequately appreciate the difficulties which opposed their final adoption. "Here, as elsewhere in education," says Dr. Pepper, "those who desire progress must have a regard for actual conditions and practical possibilities." The University of Pennsylvania had indeed made an effort at reform in 1846 by the establishment of a three-years' course, but it was forced after six years of steady diminution in the size of her classes to abandon this most commendable effort. Subsequently, after years of agitation and at times more acrimonious contention, the lengthening of the course was effected at Harvard in 1871, and later at Michigan, Syracuse, Chicago Medical College, and for a second time at Pennsylvania. During the same years the spirit of progress had effected other changes—examinations at matriculation, rational grading of the courses, and increased length of the academic year. In most of the better schools the old system of remuneration of the professors had been abolished, and practical instruction, so difficult, so costly, and yet so essential, had been made an important part of the curriculum.

All of these changes had been wrought not alone at the expense of much earnest advocacy on the part of men like Dr. Pepper, who saw clearly the need of medical education, but also at no little financial loss incurred by the smaller classes of the first few years. The change, however, was effected, and, with the example of Harvard and Pennsylvania and others, the great body of medical schools were slowly drawn to a similar advance, so that by the time of the second address, delivered on October 2, 1893, of the 118 schools from which information could be obtained, only twenty-three adhered to the two-years' standard and eight had instituted an obligatory four-years' course. In nearly all more or less satisfactory grading of the course of study had been effected. Preliminary examinations at matriculation had been instituted by many, though the rigidity of these might still be questioned. It may very well be urged that the requirement of an academic degree is beyond the present needs of advanced education; but the fault, if fault there be, lies, as Dr. Pepper shows, in the advanced age of our collegiate students. The average age at graduation is now from one to three years beyond that of students in foreign countries at their entrance upon their professional studies; and the age at which the student finally graduates and is prepared to enter practice is unquestionably too advanced. Changes should be effected by which the student may finish his collegiate studies at an earlier age; and an arrangement such as that adopted at the University of Pennsylvania, of admitting students from approved colleges who have devoted a large part of their time to biologic studies to advanced standing in the medical school is highly commendable.

The process of time and the labors and generosity of a few men, seconded by the indorsement of all thinking men of the profession have thus wrought a complete change in our system of medical education. It may be some time before the standard of the leading schools is adopted by others, but the tide has set in this direction, and the public will expect or demand a higher standard from all the schools. In this process some will surely perish, but the excessive proportion of schools to population indicates that this is desirable. Only those can and ought to survive which can offer the student all that practical, clinical, and laboratory instruction that is demanded by the modern systems of medical education. Institutions founded in places where meagerness of population or other causes make this impossible have no right to exist, and will not long continue to do so. All honor is due to the pioneers in this work who have pushed on in spite of temporary setbacks and harsh criticism, and at the greatest cost, this work of higher education. Well, indeed, and with the honest pride of personal contribution, might the learned author of this little work point to the progress and standards of educational advancement no less honorable and elevated than those of our material prosperity, presented to the nations at the time of the great Columbian Exposition in comparison with the conditions at the close of our last great exposition of 1876. During these memorable years no institution did more for the cause of higher medical education than the University of Pennsylvania, and no man more yeoman service than her distinguished guide and ruling spirit, Dr. Pepper.

EDITORIAL COMMENTS.

The Micro-Chemic Reactions of Urinary Sediments.—While the diagnostic significance of the staining reactions of various organic substances has received recognition in both biologic and histologic research, the application of this method of differentiation is capable of extension and elaboration. The schizomycetes, for instance, present such a close resemblance one to another that it is often quite impossible to recognize a given variety from its morphologic appearance. Some can be discriminated by their behavior when exposed to certain stains and decolorizing reagents, while the identity of others is only to be established by their appearance in cultures. Histologically we know that the body and the nucleus of a cell each reacts differently to stains; as do also healthy and diseased structures. Extending the application of the principle, we find that tube-casts in the urine when stained behave diversely in accordance with their chemic constitution, amyloid casts, for instance, assuming a mahogany tint when treated with iodin, and a deep blue when treated with gentian-violet. An interesting contribution to the subject of the color-reactions of urinary sediments has recently been made from the Pathologico-Chemic Institute of the Rudolph-Stiftung in Vienna by Grosz (*Internationale klinische Rundschau*, 1894, No. 41, p. 1465), who has studied the formed elements contained in urine stained with alizarin. To a drop of urine placed on a slide he adds a drop of a 1 per cent. solution of sodium alizarin sulphonate, and then covers, the examination being made after the lapse of about a minute. The sediment present is stained differently according to the reaction of its constituent elements. Thus, those of acid reaction appear yellow, those of alkaline reaction violet, and those of neutral or feebly acid reaction red. In the urine from cases of acute gonorrhea were found cylindroidal bodies of mucin, staining red, and resembling tube-casts, the likeness being increased by the presence of leukocytes and epithelial cells. Further investigation rendered it probable that these bodies (which are not visible in unstained preparations) are derived from the glandular apparatus of the urethra, and more particularly from the glands of Littré. Other long, convoluted, and hyaline cylindrical bodies, upon which are seated isolated leukocytes and epithelial cells, and which appear in unstained preparations as structures of faint contour, are derived from the prostate gland, of disease of which their presence is suggestive. They were also found in the urine passed after coitus. In contradistinction to these urethral and prostatic structures, renal tube-casts stain intensely yellow. The presence of casts is also associated with the absence of a mucoid ground-substance that stains red, and accompanies the other two. In some cases of disease of the posterior portion of the urethra leukocytes stained violet were observed, but the number of cases was not sufficiently large to establish the diagnostic significance of the observation. The opinion is expressed that the reaction of the epithelial cells progresses from acid to alkaline, from the surface to the deeper layers; so that the reaction of the sediment in the urine will indicate the nature and seat of the morbid process in the genito-urinary tract.

The Dangers of Foot-ball.—A danger of foot-ball hitherto unrecognized or disregarded is the occurrence of albuminuria, with the presence of casts in the urine, as a result of the great activity entailed by the violent exercise. A series of interesting observations upon this subject has recently been recorded by MACFARLANE (*Medical Record*, No. 1258, p. 770), who obtained a response to Heller's nitric-acid test for albumin with the urine voided by nine players immediately after a game. On standing for twelve hours there was a heavy sediment in each case and microscopic examination disclosed the presence of urates, crystals of uric acid, calcium oxalate and a large number of casts, some epithelial, a number granular and many hyaline. On examination of the urine of six of the players voided three-and-a-half hours after the game a response to Heller's test was obtained with one specimen, a response to Tanret's test in every instance, and a response to Millard's test in three. On microscopic examination a few casts, mostly hyaline, were found. On another occasion the urine of twenty foot-ball players voided immediately after the game was examined and albumin in considerable quantity found in every instance. In all casts were also found, some granular and hyaline, and in some blood-casts. There were present, besides, many epithelial cells, an abundance of oxalates, urates and crystals of uric acid, and in a few considerable blood.

The question naturally arises whether such conditions can be induced twice or oftener weekly for a considerable length of time without risk of permanent damage to the kidneys, and further whether there is not considerable danger for players already suffering with functional or organic disease of the kidneys.

Food-adulteration from an English Standpoint.—A Parliamentary Committee is seeking light on the extent and nature of food-adulteration and on the methods of preventing it. Several more or less distinguished experts have been examined at considerable length. The evidence is too bulky to be even outlined here, but among the interesting points brought out in the examination of MR. JAMES LONG, a well-known authority in dairy chemistry, was that several brands of condensed, closely skimmed milk (separator-milk) are largely sold in England, generally without due notice as to their insufficiency in fat. MR. LONG regards separator-milk as "unquestionably" nutritious, but naturally deprecates foisting it on the public as whole milk. Another point brought out was that a brand of condensed milk, labelled "Swiss Dairy," and ornamented with a scene in the Alps, is made in Ireland.

The sale of separator condensed milk seems to be much less frequent in this country; at least some analyses made lately for THE NEWS failed to discover any condensed milk notably deficient in fat.

The Transmission of Cholera by Flies.—It has been shown experimentally that flies may act as the carriers of cholera-infection. (See MEDICAL NEWS, March 25, 1893, p. 328.) The recent epidemic at Gaya gaol, in India, furnishes confirmatory evidence upon this important subject. It is related that the first case occurred in a newly-admitted prisoner, who appears to have contracted the disease on his way to the gaol. He occupied successively a number of wards, in each passing several evacuations that were not specially dealt with. The water used was beyond suspicion, and direct proof of the conveyance of cholera-organisms from the excreta to food was wanting. On the other hand, about the gaol were swarms of flies having easy access to both the intestinal evacuations and the food and milk; and bacteriologic examination of specimens of sterilized milk exposed in new vessels, to which flies were permitted access in various parts of the gaol, disclosed the presence of cholera-bacilli.

House-filters vs. Municipal Filters.—We alluded a short time ago to the exhaustive investigation into the efficiency of house-filters, the results of which are still in course of publication by the *British Medical Journal.* It is quite evident from the data furnished, as well as from those reported by other investigators, that wherever a general filtration-system is available it affords the safest means of securing pure water. However anxious the householder may be to obtain a good house-filter there is no certainty of getting one, nor is the maintenance of a filter in proper condition always an easy matter.

The municipality that does not furnish its citizens with an abundant supply of perfectly clear and wholesome water fails in one of the fundamental objects of human society. There will be no market for a house-filter in any city whose affairs are well administered.

For the Boy and His Father.—Every parent has felt the duty of instructing his son as regards sexual matters, especially if he suspects bad habits, and he has also felt the solicitude lest attempted instruction should arouse curiosity when it did not yet exist, and thus do harm instead of good. To steer safely between the double danger has been often tried, and almost as often the attempt has failed. It is an exasperatingly difficult thing to do—in print. In a little monograph (*Temptations, Habits, Character*, Arena Publishing Co.), Dr. Wm. M. Capp, of Philadelphia, has by all odds succeeded better than any previous writer known to us in the task, and we cordially commend the pamphlet to perplexed parents and medical advisers who fear their young men are excited and curious about sexual matters, or that they may be acquiring the morbid knowledge that may lead to vicious and depraved habits.

Typhoid Fever and Creameries.—Some English journals are discussing the danger of the spread of typhoid fever by means of creameries. These are establishments to which many farmers bring milk, which is then mixed, skimmed by centrifugal machines, and the cream made into butter. It is well known that the addition of a small amount of infected material to a large volume of milk or other nutritive fluid is followed by rapid and extensive multiplication of the pathogenetic bacteria; hence, if a single lot of only a few quarts is infected, a wide distribution of disease may take place. The suggested danger is well worth noting, and is another argument for farm-inspection and an indication that the mere analytic control of milk is of minor importance.

Medical Martyrs.—The list of medical men whose lives have been sacrificed in the pursuit of their profession is a long and constantly growing one. One of the most recent additions is that of a young French physician named Masson, who, having been called upon to attend a poor family attacked with typhoid fever, and situated amidst squalid and filthy surroundings, with no one to minister to their needs, himself undertook the task of caring for the patients. He succeeded in making them fairly comfortable, but was attacked with typhoid fever and died. Cases of not dissimilar character must be familiar to many, both within and without the medical profession.

SELECTIONS.

THE BUCCILINGUAL FRAGMENT.

FOR many years it has appeared to the general public that this institution, founded by a man like Ezra Cornell and largely saved by a man like Henry W. Sage, has been conducted by and in the interests of a gigantic sporting fraternity, comprising about one-fourth of all the students. Among them are good men and earnest scholars. Among them also are evidently some who accept the doctrine recently enunciated by the President of Princeton: "I appreciate scholarship as much as anyone, but realize the fact that all of those who go to college do not desire to become fine scholars." From their ostensible vocation, study, they find time for numerous avocations, more or less laudable in themselves, but seldom conducive to scholarship. They are pre-eminently the patrons of inter-collegiate athletics, not so much by playing themselves as by attending games and, until perhaps very recently, betting upon the results. They commonly have plenty of money, not often self-acquired. They contribute liberally to athletic funds; they also, however, demand that others should do the same. They clamor for aid from the antipathetic in paying the salary of a professional trainer, and in the same term spend what would pay that salary many times over for the luxury of witnessing games in distant cities. They convert the college papers into sporting gazettes. They claim to represent the institution before the public. They assume to constitute the "student body," whereas they are merely a buccilingual fragment thereof.—*Prof. B. G. Wilder, of Cornell University.*

CONGRESS AND A NATIONAL BUREAU OF HEALTH.

THE report which the Committee on National Quarantine made to the Academy of Medicine concerning their efforts to get Congress to pass a law establishing a National Bureau of Health furnishes a striking commentary upon Congressional methods. A bill was prepared which received the approval of the medical press, the leading medical authorities, boards of trade, chambers of commerce, the chief newspapers, in short, of the entire body of intelligent and expert opinion of the country; yet the committee which had it in charge could not be induced to report it. One would think that with such an impressive body of public opinion in favor of a a bill the members of the committee would be glad to do all they could to hasten its passage; but scarcely one of them showed the slightest interest in it. What was the reason? We presume that the chief reason was political, and that there was at Washington last year, as there has been every year before since this subject was first broached, a powerful "pull" in favor of the perpetuation of the present quarantine system at New York. That "pull" ought not to be good after January 1st, but we presume it will be useless to hope for any action during this short session. The new Congress ought to show itself more amenable to reason, and ought to be willing to grant the passage of a measure which is in the interest of the health of the whole country.—*N. Y. Evening Post.*

REVIEWS.

A SYSTEM OF GENITO-URINARY DISEASES, SYPHILOLOGY, AND DERMATOLOGY. By VARIOUS AUTHORS. Edited by PRINCE A. MORROW, A.M., M.D., etc. With illustrations. Vol. iii. Dermatology. 8vo., pp. 976. New York: D. Appleton & Co. 1894.

THE third and concluding volume of this work is fully equal in style and appearance, as well as in the quality of the matter contained in its pages, to those which have preceded it. Its subject is one which has been greatly extended by modern research. The editor says in his preface: "A comparison of the table of contents of this volume with that (*sic*) of the text-books on dermatology of a few years ago will show that no fewer than forty diseases are now recognized as clinical entities which were then unknown or identified with other dermatoses."

The classification adopted is practically that of Hebra as modified by Crocker. Perhaps this is as available as any; but it is not without its defects. We find placed among the inflammations a number of disorders in which inflammatory phenomena are by no means essential, but are sometimes almost or altogether wanting, such as varicella, variola, and vaccinia. Herpes should, in our opinion, rank with the neuroses, as should also symmetrical gangrene (Raynaud's disease). And we believe that affections of coccidian origin might properly be placed among those recognized as parasitic.

The material of the article on feigned skin-diseases would be more appropriately, we think, distributed throughout the work in connection with the diagnosis of the special disorders which may be counterfeited.

The authors, twenty-seven in number, have presented the subjects allotted to them in a readable form and in accordance with the generally accepted views of the day. We feel constrained, however, to say that the book, as a whole, is not one adapted for the use of beginners in dermatology, or as a work of reference. It is not in any sense exhaustive or encyclopedic. For physicians who have had some opportunities for the study of diseases of the skin it will serve well as a guide for further reading and investigation.

A very interesting article on leprosy is contributed by the editor, who has had unusual advantages for observation of this disease during a visit paid by him to the Sandwich Islands.

A more uniform and complete system of bibliographic references would have added much to the value of this work. So also would a table of formulæ for the various remedies spoken of in the text. Thus, Lassar's paste (composed of salicylic acid, zinc oxid, powdered starch, and vaselin) is mentioned repeatedly, but we have been unable to find that the formula for it is anywhere stated.

The index is very imperfect. Sometimes the synonyms are given, sometimes omitted altogether. For example, under "hydroa" we are referred to a very brief article on p. 204, chiefly devoted to one form of the disease—the *hydroa puerorum* of Unna; but we are not referred to p. 166, where the term appears as a synonym of dermatitis herpetiformis, and is much more important.

As a rule, the illustrations are remarkably good. We venture to hope that in another edition they may be extended so as to include representations of the micro-organisms which play so prominent a part in many of the affections described.

Physiology for Beginners. By M. Foster, M.A., M.D., F.R.S., and Lewis E. Shore, M.A., M.D. New York and London: MacMillan & Co., 1894.

There was a time, not so very long ago, when the furnishing of text-books in American schools was let out by the job-lot to some one publishing firm which had the necessary political pull, and the professional school-book writer was very much in evidence, ready to write a book on any subject, no matter how foreign to him. Within the last few years a desire for a higher grade of books for school-children has been slowly cultivated, and men of recognized standing in their respective branches are engaged to write such books. Unfortunately the university professor, following his own special line of research, is not always able to descend from his lofty pedestal, from which he lectures to mature men or women, to the needs and comprehensions of small children, and thus it happens that what he writes, in spite of his thorough knowledge of the subject, is not best adapted for primary schools; he arranges the matter treated in the same manner as he presents it to his own students, and not according to the methods of the so-called new education now followed by all competent teachers. Prof. Foster's little book is excellently written and in its present form a very valuable guide for teachers who know the subject thoroughly; but if the different chapters would be rearranged by some up-to-date school-teacher well versed in modern educational methods, and a good complete glossary added to each, the book would increase in value tenfold, and really be a "physiology for beginners," which it is not in its present form. Modern education demands that instruction should proceed from the known to the unknown, that there should be a thought in the child's mind upon which the teacher can build another thought, and a university professor is too prone to forget that a young child, a beginner in the fullest sense of the word, has only one definite and tangible thought in relation to physiology, and that is *food*, not blood, not chemic action.

Practical Urinalysis and Urinary Diagnosis: A Manual for the Use of Physicians, Surgeons, and Students. By Charles W. Purdy, M.D., Queen's University; Fellow of the Royal College of Physicians and Surgeons, Kingston; Professor of Urology and Urinary Diagnosis at the Chicago Post-Graduate Medical School; author of *Bright's Disease and Allied Affections of the Kidneys;* also of *Diabetes: Its Causes, Symptoms, and Treatment.* With numerous illustrations, including photo-engravings and colored plates. 8vo., pp. xiv, 351. Philadelphia: The F. A. Davis Co., 1894.

The time has passed when it was necessary to emphasize the importance of a study of the urine for diagnostic purposes. Perhaps even in a greater degree than physical examination, investigation of the urine is made as a routine practice—for there is danger in resorting to urinalysis only when the symptoms or the very obscurity of a diagnosis suggests such an examination. This contribution of Dr. Purdy's is a useful addition to the literature of urinary examination. It is well and intelligently written, and while taking cognizance of new tests, indorses only those that practical experience has shown to be reliable. The arrangement is a convenient and logical one. The various constituents of the urine, both normal and abnormal are considered successively as to their chemic nature and composition, their source in the economy, the significance of their increase or decrease, the relation of these changes to metabolic processes, food-supply, physical surroundings and tendency toward disease, with the most approved methods of detection and determination. Finally, a concise description is given of the special features of the urine that indicate the existence of special pathologic processes in the economy, together with a brief enumeration of the principal symptoms of each disease, and reference to their nature and etiology. The book is well printed and well made, and measurably free from error. By a strange perversion, the compositor has insisted upon spelling urinalysis "uranalysis."

ATTFIELD'S CHEMISTRY. NEW (14TH) EDITION. CHEMISTRY, GENERAL, MEDICAL, AND PHARMACEUTICAL. By JOHN ATTFIELD, M.A., PH.D., etc., Professor of Practical Chemistry to the Pharmaceutical Society of Great Britain, etc. Fourteenth edition, specially revised by the Author for America to accord with the new U. S. Pharmacopeia. Royal 12mo, 794 pages, 88 illustrations. Philadelphia: Lea Brothers & Co., 1894.

WITH a work so long in favor and so widely known as this, the reviewer can do little else than chronicle from time to time successive editions. The present edition maintains the merits of the work and adheres to the arrangement of subjects that have been so long characteristic of it. It was hardly to be expected that an English chemist would adopt the American spelling of chemic terms, especially in view of the attitude of the present pharmacopeia, but it is certainly to be regretted that reforms in the nomenclature which have been officially advised by an international convention and long adopted by both English and American chemists should be wholly ignored. We find, for instance, "hydrate" used for "hydroxid," "glycerin" for "glycerol," "resorcin" for "resorcinol." We note also the spelling "albumen," instead of "albumin." It certainly seems strange that so able a chemist should persist in using the termination "en," which has no significance in chemistry, in the face of the employment of "in" for all analogous bodies. Albumin is of course classed by our author with casein, fibrin, etc., yet he does not seem to see the incongruity of using a different termination. This is all the more serious because the term "albumen" has a specific meaning in biology.

The work exhibits the excellence in printing and care in proof-reading that are usual with this publishing firm. It will no doubt find ready acceptance, and it will be the duty of the reviewer at no distant period to chronicle the appearance of the fifteenth edition, in which we hope to see some evidence of the effect of the leaven of spelling reform.

SAUNDERS' QUESTION COMPENDS. NO. 24. ESSENTIALS OF THE DISEASES OF THE EAR. ARRANGED IN THE FORM OF QUESTIONS AND ANSWERS. PREPARED ESPECIALLY FOR STUDENTS OF MEDICINE AND POST-GRADUATE STUDENTS. By E. B. GLEASON, S.B., M.D., Clinical Professor of Otology, Medico-chirurgical College, Philadelphia. Surgeon in charge of the Nose, Throat and Ear Department of the Northern Dispensary, Philadelphia. Philadelphia: W. B. Saunders, 1894.

THIS little work is up to the standard of this compend series, yet it is a mistake to occupy too much space in a book of this size with cuts of apparatus and structures with which even the student is familiar. The section devoted to rhinoscopy is good; the same can be said of the portion treating of diseases of the middle ear. In dividing the space for the subjects treated it seems scarcely necessary to devote almost one-seventh of the book to the anatomy of the ear. The illuminating headlight, given as that of the author, is good, yet it is only a modification of the now common electric headlights used. The Hirschmann light answers the same purpose and is practically the same. The book covers pretty thoroughly the subject, and while not presenting much that is new, yet the author's questions are to the point, and his answers are clear and concise.

TEXT-BOOK OF MEDICAL AND PHARMACEUTICAL CHEMISTRY. By ELIAS H. BARTLEY, B.S., M.D., Professor of Chemistry and Toxicology in Long Island College Hospital, etc. Third edition, revised and enlarged, with 84 illustrations. Octavo, pp. 684. Philadelphia: P. Blakiston, Son & Co., 1894.

CHEMIC knowledge must be gained in the laboratory. The teacher and the text-book can only help the student in his studies. Among thoroughly helpful text-books the one before us deserves high commendation, and the fact that it has reached a third edition shows that its value is appreciated. The preliminary sections on physics, the concluding sections on digestion and excretions, with tests for stomach-contents, urine, and feces, add much to its usefulness to students and to physicians. A glossary and a good index complete the list of its merits.

CORRESPONDENCE.

GUAIACOL TOPICALLY AS A PROPHYLACTIC AGAINST DIPHTHERIA.

To the Editor of THE MEDICAL NEWS,

SIR: While admitting the difficulty of estimating the true value of an agent used as a preventive against an infectious disease, I desire to urge upon the profession the topical application of guaiacol as a possible—yes, a probable—prophylactic against diphtheria in the cases of attendants upon diphtheria-patients, and of children and others residing in the same house with diphtheria-patients.

If an excessive quantity is not used, guaiacol may be applied harmlessly, in full strength, even to the throats of children; but for children it is, I think, best to dilute it one-half or two-thirds, according to the age of the child, with olive oil or liquid petrolatum. Very sensitive throats may be previously touched or sprayed with a solution of cocain (from 2 per cent. to 5 per cent.).

The guaiacol, which should be a pure preparation (Merck's is reliable), is best applied with cotton wad, and by quick motion, first to one tonsil, immediately afterward to the other tonsil, and after an interval of two or three minutes to the pharynx. Some burning or smarting is caused by each application. This, however, passes off in the course of a minute or two, or, if unexpectedly severe, may be relieved by ice or iced water. Latterly I have used as a diluent for guaiacol a five per cent. solution of menthol in liquid petrolatum, and the peculiar cooling effect of the inhalation of air after the use of mint seemed to be an advantage. There is no caustic or escharotic effect from pure guaiacol. Impure preparations cause an undesirable eschar more or less opalescent according to the character of the impurity.

The application may be repeated daily or at longer intervals, or not at all, according to circumstances.

Very truly yours,
SOLOMON SOLIS-COHEN.
219 S. SEVENTEENTH ST., PHILADELPHIA.

NEWS ITEMS.

Charcot Memorial.—The pupils and former associates of Charcot in Paris and throughout France are engaged in raising a fund for the erection of a bronze statue of the great neurologist in the Salpêtrière. This movement is now receiving cordial and material support in Germany, in England, and in Italy, as well, of course, as in France.

It has therefore seemed desirable to the Neurological Societies of New York and Philadelphia that the profession in America should join in this testimonial as a tribute to the eminent services of Charcot in neurology and medicine.

For this purpose a committee has been appointed to bring the matter to the attention of the profession and to receive contributions, which will be duly acknowledged and forwarded to the central committee in Paris.

All who desire to contribute to the success of this undertaking are requested to send their subscriptions to the members of the committee nearest them or directly to the treasurer, Dr. C. A. Herter, 819 Madison Avenue, New York, before the first day of February, 1895. The committee is constituted as follows:

For New York: E. D. Fischer, M.D., E. C. Seguin, M.D., M. A. Starr, M.D., C. L. Dana, M.D., C. A. Herter, M.D.
For Philadelphia: S. Weir Mitchell, M.D., Wharton Sinkler, M.D., Chas. K. Mills, M.D.
For Boston: J. J. Putnam, M.D., P. C. Knapp, M.D.
For Baltimore: William Osler, M.D.
For Chicago: Archibald Church, M.D.
For St. Louis: C. H. Hughes, M.D., F. R. Fry, M.D., L. Bremer M.D.
For Montreal, Canada: James Stewart, M.D.
For Rochester: E. B. Angell, M.D.
For Buffalo: J. W. Putnam, M.D.
For Pittsburg: Theodore Diller, M.D.
For Denver: Howell T. Pershing, M.D.
For San Francisco: J. D. Hirschfelder, M.D.

The Philadelphia Neurological Society has voted the sum of $150 as its contribution to the contemplated memorial to Charcot.

Dr. St. John W. Mintzer, who rendered good professional service during the Civil War and who for a time resided and practised medicine in Philadelphia, died on December 26, at his home, China Hall, Bucks County, after a protracted illness, at the age of sixty-two years.

The Dominion Medical Monthly.—Dr. W. H. B. Aikins has withdrawn from the publication of the *Dominion Medical Monthly*, and Drs. J. H. Burns, John Ferguson, G. Sterling Ryerson, A. B. Atherton, and Albert A. MacDonald from the collaborating staff.

F. A. Fluckiger, the distinguished pharmacologist, died recently at Berne, at the age of sixty-six years. His contributions to materia medica and pharmacology were numerous and valuable.

Prof. K. Weil has been made Professor of Surgery in the German University of Prague, in succession to Gussenbauer, elected to the chair formerly occupied by Billroth.

A Special Course in Regional Surgery was begun at the Masonic Hospital of Chicago, by Dr. G. Frank Lydston on January 7th, and will be continued on subsequent Mondays, on the following subjects: "Surgery of the Prostate, Bladder, and Kidneys, including Calculus;" "Appendicitis;" "Surgery of the Rectum and Urethra;" "Varicocele." The course is open to members of the medical profession.

BOOKS AND PAMPHLETS RECEIVED.

Third Annual Message of Edwin S. Stuart, Mayor of the City of Philadelphia, with Annual Report of the President of the Department of Charities and Correction. For the Year ending December 31, 1893. Philadelphia: Dunlap Printing Co., 1894.

Paralysis of the Eye-Muscles of Central and Peripheral Origin. By A. Friedenwald, M.D. Reprinted from the Maryland Medical Journal, 1894.

Beri-beri, with Report of Cases. By J. M. Anders, M.D., Ph.D. Reprinted from the Medical Bulletin, 1894.

The Treatment of Erysipelas. By J. M. Anders, M.D., Ph.D. Reprinted from the Therapeutic Gazette, 1894.

L'Ichthyol dans le Traitement des Urethrites et des Cystites. Par le Dr. Roberto Villetti. Pamphlet. Rome: Imprimerie Innocenzo Artero, 1894.

Ueber die Anwendung des Ichthyol bei Wunddruck der Füsse. Von Dr. Leopold Herz. Aus dem Aerztlichen Central-Anzeiger, 1894.

Psorospermosis Cutis. Von Dr. A. Ravogli. Sonder-Abdruck aus Monatschefte für Praktische Dermatologie, 1894.

Pregnancy after Ventral Fixation of the Uterus. A Report of Four Cases. By George M. Edebohls, M.D. Reprinted from the Transactions of the New York Obstetrical Society, 1894.

Rheumatic Conjunctivitis. By A. L. Hodgdon, M.D. Reprinted from the Maryland Medical Journal, 1894.

Some Reasons for the Performance of Circumcision on all Male Infants. By A. L. Hodgdon, M.D. Reprinted from the American Medico-Surgical Bulletin, 1893.

Diagnostic Palpation of the Appendix Vermiformis. Cases of Appendicitis. By George M. Edebohls, A.M., M.D. Reprinted from the American Journal of the Medical Sciences, 1894.

Thirtieth Report of the Trustees of the Boston City Hospital; with Report of the Superintendent, the Medical and Surgical Statistics, Rules for Admissions and Discharges, Prospectus of Training School for Nurses, Rules for the Convalescent Home, etc., for the Year, February 1, 1893, to January 31, 1894. Boston: Rockwell & Churchill, 1894.

World's Fair. Jamaica at Chicago. An Account Descriptive of the Colony of Jamaica, with Historical and Other Appendices. Compiled under the Direction of the Hon. C. J. Ward, C.M.G., Honorary Commissioner for Jamaica. New York: Wm. J. Pell, 1893.

Chemistry: General, Medical, and Pharmaceutical, Including the Chemistry of the U. S. Pharmacopeia. A Manual of the General Principles of the Science, and their Applications in Medicine and Pharmacy. By John Attfield, F.R.S. Fourteenth edition. Philadelphia: Lea Brothers & Co., 1894.

A Manual of Hygiene. By Mary Taylor Bissell, M.D. New York: The Baker & Taylor Co., 1894.

Transactions of the Texas State Medical Association. Twenty-sixth Annual Session, held at Austin, Texas, April, 1894. Galveston: Knapp Brothers, 1894.

SYMPHYSIOTOMY, WITH A SUCCESSFUL CASE.[1]

BY W. WINTERBERG, M D.,
OF SAN FRANCISCO, CALIFORNIA.

THE operation of symphysiotomy was first suggested by Pineau in his work on *Surgery* in 1598. La Courvée first performed it on the dead body in order to save the child in the year 1655, and Plenk did it for the same purpose in 1766. In 1777 Sigault first proposed the operation to be done on the living, and Ferrara was the one to carry out practically the proposition; still Sigault is generally considered to be the first symphysiotomist. In the eighty-five operations performed from that time to 1858 there was recorded a mortality of thirty-three per cent., a result which was not very favorable for the dissemination of the operation. It is, therefore, not very surprising to find that with the year 1858 it had practically died out.

It was revived in Italy in 1866, and performed in seventy cases within the following twenty years, with a mortality of twenty-four per cent.

Pinard was the first to follow the example set by the Italians, and in 1892 he performed symphysiotomy for the first time in Paris since its abandonment in 1858, and soon the other European countries followed his example.

In this country, Dr. Coggin, of Freedman, Alabama, now of Athens, Georgia, operated successfully for mother and child only seven weeks later than Pinard. Dr. Barton Cooke Hirst, Dr. Jewett, and Dr. Garrigues were the first operators in Philadelphia, Brooklyn, and New York, respectively. On the Pacific coast the first symphysiotomy was done by Dr. Holmes, of Portland, Oregon; and in California my own case has been the first, so far as I have been able to ascertain.

The purpose for which this operation was originally devised is to deliver a living child *per vias naturales* in certain forms of contracted pelvis in which formerly Cesarean section was imperative to accomplish this end. The question, therefore, obtrudes itself: What are the advantages and disadvantages of this operation as compared with conservative Cesarean section?

In studying the latest statistics of the results of the two operations we find that the danger to the mother is far greater in the last-mentioned than in the first. In Europe, in the hands of the best operators, the maternal mortality has been about ten per cent. in ninety-nine cases of Cesarean section, and in Leipzig there have lately been recorded fifty-four cases with but three deaths—less than six per cent.; but in this country the results have not been so favorable. A table compiled by Dr. Harris, of Philadelphia, shows the following results, beginning only with the year 1887, and omitting the period from 1882 to 1886:

Operations of	No.	Women recovered.	Children saved.
1887	8	5	8
1888	13	5	13
1889	9	6	8
1890	17	13	16
1891	10	7	6
1892	12	9	12
1893	10	6	6
	79	51	69

In a total of 79 operations performed there are 28 maternal deaths, or a mortality of 35.5 per cent. Taking the year 1893 alone, we find four deaths out of ten—a mortality of 40 per cent. This is certainly a frightful mortality, and so much the more discouraging, as there does not seem to be any improvement at all that might have been reasonably expected from an improved technique and a rapid advance in aseptic surgery. As to the infantile deaths, we see by the same table a mortality of about 12.5 per cent.

The earlier statistics of symphysiotomy show a much greater mortality than would have first been anticipated. Thus, Dr. Barton Cooke Hirst, in an address delivered before the Washington Obstetrical and Gynecological Society, November 17, 1893, states that in 212 operations since 1887 there have been 27 maternal deaths, a mortality of 12.73 per cent., while the deaths of the infants raise up their mortality to a little over 28 per cent.

Varnier (*Annales de Gynécologie et d' Obstetrique*, 1893, p. 241) tabulates 124 cases, as follows: Maternal deaths, 12; infantile deaths, 32. Of the 12 mothers lost, 8 died from causes entirely disconnected from the operation; of the remaining 4, one died of septicemia, one of sphacelus of the vulva and vagina, one of cellulitis and peritonitis due to the use of the saw and to forcible introduction of hand and arm in order to effect version; one of hemorrhage, shock of operation, and of lacerations of perineum, vulva, and bladder. Of the infantile deaths, five cases should be eliminated in which the operation had been done in place of embryotomy. Of the remaining 27 deaths, 7 were due to causes not related to the operation, 11 to mishaps with forceps or in version, 7 in succession to incomplete section, 1 to prolonged extraction due to distortion of the right arm, 1 to a cerebral lesion owing to prolonged pressure on the head. The later statistics of Morisani give, in 55 cases, 2 maternal and 2 infantile deaths; and Zweifel (*Centralblatt für Gynäkologie*, 1883, No. 22) reports 14 cases from the Leipzig clinic with favorable results to mothers in all. One child died from asphyxia, and one from pneumonia two days after birth.

---

[1] Read before the American Medical Association, at San Francisco, June, 1894.

Puech reports 73 cases, with a maternal death-rate of 4.1 per cent., and 24.6 per cent. of infantile deaths; and Pinard operated in 19 cases, with no maternal deaths; 3 children died, but not directly from the operation. Owing to the rapid spreading of the operation all over the world within the last year it is impossible to compile an accurate statistical table; but the last figures seem to justify the conclusion that the results both to mother and child are rapidly improving, and that as compared with Cesarean section the balance of safety is decidedly in favor of symphysiotomy. Leopold himself, who certainly cannot be said to be prejudiced against Cesarean section, holds that the mortality in this operation is, and always must be of necessity, greater than in symphysiotomy, and the latter operation ought to take the place of the former in all those cases in which it is practicable.

Apart from the greater safety which it gives to the mother, symphysiotomy certainly has the advantage of greater simplicity and easier execution, and it is unintelligible to me how Dr. Barton Cooke Hirst can claim that the lower maternal death-rate is the *only* reason which should make it the operation of election in practicable cases. The much more complicated apparatus necessary for the performance of Cesarean section certainly is an objection to it, as compared with the simple outfit required for symphysiotomy.

It is true that successful Cesarean sections have been performed in former ages with the most primitive instruments, and without any of the paraphernalia that we now think indispensable for the performance of a capital operation, not to speak of trained assistants, or our whole antiseptic apparatus. But, let me ask, is there any one who would feel safe if he had to do a Cesarean section with no more instruments, no more antiseptic apparatus, no more skilled assistants, than are actually necessary in order to perform symphysiotomy? I believe not. If we could treat all our patients in well-managed hospitals, where everything needed for a capital operation is always in readiness, I might concede that the respective outfit necessary to perform either operation did not deserve much consideration; but as long as we sometimes have to operate in out-of-the-way places, with the most unfavorable surroundings, I think it a great help to simplify matters as much as possible; and I think, likewise, that symphysiotomy is the operation that can safely be done with the simplest means. As to the operation as such, it is certainly easier for the operator, and the directly opposite view of some well-known operators to the contrary notwithstanding, I maintain that it requires much more practical experience and surgical skill to perform Cesarean section than symphysiotomy. As a matter of course, every medical man cannot possibly have an opportunity to study the technique of Cesarean section, and it is, therefore, of great value to be in possession of a simple method that will enable us to dispense with the more dangerous, the more difficult, and the more complicated operation in certain well-defined cases of labor, and we all must be prepared to face such cases sooner or later.

Simple, easy, and safe as the operation of symphysiotomy is in itself, it cannot claim these advantages when the question as to the after-treatment arises. This is undoubtedly one of the weakest points of the operation, and it is very likely due to this weakness that Schauta would prefer Cesarean section to symphysiotomy in *private* practice. The management of the case after delivery requires close attention and good nursing, such as are not always to be had outside of hospitals; and I perfectly agree that the after-treatment of a case of Cesarean section is much simpler and easier.

Of some other considerations against symphysiotomy ought to be mentioned the likelihood of serious tears in the anterior vaginal wall, the urethra and bladder, which, of course, are very serious accidents, and should they occur much oftener than they actually do would soon make the operation decidedly undesirable. But I think that with an improved technique we shall soon learn how to avoid these accidents.

The objection that has been raised against symphysiotomy on the ground that the forceps or version may still be required to effect delivery after the operation has been done is hardly serious enough to deserve notice. One might just as well object to Cesarean section on the ground that after opening the abdominal wall there was still another operation left to be done, namely, that of opening the uterus and removing the fetus.

Dr. Barton Cooke Hirst, in the same address referred to before, mentions as considerations against symphysiotomy: the need of good assistants; the absolute necessity of as thorough asepsis as is demanded in abdominal surgery. As to the first of these two points, good assistants are always desirable in every surgical operation; but in my opinion, and to judge from the experience that I have had so far, there are few other operations that could be satisfactorily accomplished with so little assistance as this one. In the case in which I operated myself I was assisted only by my son, a medical student in his second year, Dr. Dodel administering the anesthetic, and still there was no serious difficulty encountered, with the exception that the bed upon which the patient rested broke down toward the latter part of the operation, and I had to finish with the mattress resting on the floor. I do not think that a staff of trained assistants would have prevented this accident. As to the thorough asepsis demanded, I do not think that that should be called an objection, unless we apply it to every surgical case.

It is the duty of every conscientious operator to use all possible means to prevent infection, no matter what operation he may be performing. The same antiseptic precautions that are imperative for a simple case of labor ought to be sufficient for a case of Cesarean section or symphysiotomy. Aseptic surgery, in order to be effective, must be thorough, and there is absolutely no excuse for a relaxation of our vigilance on the ground that we just do not happen to open the peritoneal cavity.

Quite a different objection to symphysiotomy has been raised by Walcher (*Centralblatt für Gynäkologie*, 1893, No. 25), that is, the condition of the symphysis after the operation. He claims that in a number of cases the operation will result in either a loose or an ankylosed joint. The design of the symphysis, according to him, is to form with the sacro-iliac joint an elastic springy connection between the thighs and vertebral column. This is so constructed that the haunch-bones and sacrum do not move in one axis, but that the pelvic planes, *converging* from behind forward, form two coöperating axes, which for the execution of a movement require a sliding of the haunch-bones at the symphysis. If the symphysis be ankylosed, the movement of the sacro-iliac joint is lost. When this occurs the jar in walking will be directly transferred to the spine, a most important point in the movements and carriage of the patient. A loose joint lessens safety. Admitting the correctness of this theory, it is still impossible to agree that the occasional occurrence of either disorder should be taken as a serious objection to the operation. A loose joint will not infrequently result from natural labor; besides, I think that proper care and an improved technique of the after-treatment will altogether do away with this complication. In the great majority of cases reported, union took place in a surprisingly short time, and patients were able to walk with a steady gait as early as three weeks after the operation. As far as ankylosis is concerned, it is difficult to say how this could be prevented. Fortunately it seems to occur very rarely. I have not found a single case of that kind reported in the literature accessible to me.

The fundamental indication for the operation is given by such a disproportion between the head of the fetus and the pelvic diameters that delivery would be impossible without recourse to embryotomy or Cesarean section.

It would lead me too far if I should attempt a detailed description of the different kinds of contracted pelves; and I am sure it would be "carrying owls to Athens," for I am not addressing tyros in medicine now. Suffice it to say that it is principally in those varieties of contracted pelvis which are known as the flat and the rickety flat pelvis in which the operation finds its application. Next to these ought to be mentioned the generally contracted, the kyphotic, and the funnel-shaped pelvis. In the ankylotic pelvis the operation is contraindicated by reason of the immobility of the sacro-iliac synchondrosis.

The availability of the operation depends upon the length of the antero-posterior diameter of the pelvic inlet in the flat and generally contracted pelvis. In the funnel-shaped, as well as in the kyphotic, variety the length of the transverse diameter of the pelvic outlet will furnish the indication. The biparietal diameter of a full-grown child averages 9.25 centimeters, and taking into consideration its compressibility, amounting to about 6 mm., it can be reduced to 88 mm.

Now, supposing we have to deal with the pelvis having a conjugata vera of 67 mm., we must gain sufficient space by the separation of the symphysis for the passage of the head. By different experimenters it has been shown that the increase in length of the conjugata vera is one-fourth of the distance between the pubic bones, so that with a separation of 8 centimeters we should gain 2 centimeters in the antero-posterior diameter. To go beyond this limit would jeopardize the safety of the sacro-iliac joints, as has been clearly demonstrated by repeated experiments. Adding this to the original 67, and taking for granted the statement of Dr. Garrigues, who says that the head enters to the extent of about 6 mm. in the gap, we have a clear gain of 26 mm., which will give a conjugata of 93 mm. for the passage of a head, the biparietal diameter of which may be reduced by compression to 88 mm. This calculation shows that delivery can be easily effected by symphysiotomy when the true conjugate does not measure more than 67 mm. This length is now generally accepted as the lower limit at which the operation is considered feasible. The upper limit is placed at 88 mm. by the majority of operators, while Dr. Garrigues advocates 95 mm. in a flat, and 11 centimeters in a generally contracted pelvis, on the ground that the latter offers the same resistance as a flat pelvis with a conjugate 13.5 mm. (0.5 inch) shorter.

This proposition of Dr. Garrigues is unintelligible. It certainly is paradoxic to talk of a generally contracted pelvis with a conjugata vera of 11 centimeters. The normal length of the true conjugate is 11 centimeters, therefore, with one diameter perfectly normal, a *general* contraction cannot be said to exist in such a pelvis.

It seems to me that taking the measures by Dr. Garrigues as the upper limit would mean to give a larger scope to the operation than it ought to be allowed. By early or so-called prophylactic version, many cases of labor may be terminated safely to mother and child, when the true conjugate is barely 8 centimeters in length, and, therefore, whenever practicable, it ought to be resorted to in preference to symphysiotomy. Still, in my opinion, it would be premature to give a final decision in regard to this point. Possibly, after some time, when the comparative safety of symphysiotomy will have been demonstrated beyond the possibility of a doubt, there may be a change in the opinion of those who caution against a too liberal use of the newly-revived operation.

In the rarer forms of contracted pelves, known as the kyphotic and the funnel-shaped pelvis, we find the principal shortening in the transverse diameter of the pelvic outlet, either alone or combined with a shortening of the antero-posterior diameter; while the pelvic inlet remains normal, or pretty nearly so. It is in this kind of pelvic contraction that symphysiotomy will be more useful and effective than in the varieties mentioned, because of the direct ratio which the increase in the length of the transverse diameter bears to the amount of diastasis of the pubic bones; in other words, every inch of separation means an additional inch in the length of the diameter.

The upper limit for the indication of symphysiotomy in these cases I should place at the same degree of contraction in the transverse diameter of the pelvic outlet that was decisive in the conjugate of the flat pelvis; because the proportion between cephalic and pelvic diameter remains the same, the transverse diameter of the pelvic outlet corresponding exactly to the antero-posterior of the pelvic inlet in a normally-developed pelvis. As to the lower limit, I think it could safely be placed below sixty-seven mm., if such an amount of contraction should ever occur. Supposing we had to deal with a transverse diameter of six centimeters, a diastasis of five centimeters would be sufficient to restore the normal length.

Besides the foregoing there are other indications for symphysiotomy. Thus it has been performed for the removal of a tumor from the pelvic cavity, and has been proposed for impacted mento-posterior face-presentation. Albaran reports a case in which he did the operation successfully in order to facilitate the removal of recurrent epithelioma of the bladder. An abnormally large head would furnish another indication for the operation.

There are two methods of operation in use, the subcutaneous and the open,—the first advocated by Morisani, the second by Pinard. Either method has its advantages and its disadvantages. For the open method it is claimed that one can see exactly what he is doing, and in case of hemorrhage have easier control over it. The subcutaneous method has the undeniable advantage of a smaller wound. I should prefer the subcutaneous method for those cases in which the joint takes a straight course and can be easily divided with the knife, while the open method would be preferable when, in the presence of a zigzag line of the joint or of ossification, the chain-saw would have to be employed. Still, in the absence of a larger experience, I must leave the question *sub judice*.

Leopold and others teach that the division of the subpubic ligament is useless after the joint has been opened, and that therefore this structure ought not to be cut. This may possibly be good practice in cases of flat pelves in which we only have to deal with an abnormally short conjugate, but I fail to see what we can gain by his method in those cases in which the transverse diameter of the pelvic outlet is contracted. It is evident that a separation of the upper ends of the bodies of the pubic bones, while the lower ones are still being firmly held together at the vertex of the pubic arch by the subpubic ligament, could only result in a further approximation of the tuberosities of the ischium, if they could follow the strain brought to bear upon them by a forcible separation at the upper end, and therefore I think that these cases imperatively demand the division of the ligament. Besides, general experience seems to contradict Leopold's view.

The patient is to be placed in the lithotomy-position, with the flexed thighs gently abducted, and then an incision of variable length is made, according to the method chosen for the operation. For the subcutaneous, a longitudinal incision three or four centimeters in length is made in the median line, terminating about one centimeter above the symphysis. After the division of the pyramidalis muscle the finger is introduced to the lower end of the symphysis, and under its guidance the joint is cut through with a probe-pointed bistoury, from behind forward and from below upward. For the open method the incision is begun about two centimeters above and in front of the symphysis, is carried down to the root of the clitoris, or is made to deviate to the left of that organ and continued into the vulva between the labium majus and minus. The joint may then be opened by cutting from without inward and from above downward, or in the manner described. The wound in either case ought to be well protected with a pad of iodoform-gauze. After delivery, which may be effected by expression or the forceps, the wound ought to be carefully closed by close silkworm-gut sutures (which ought to be passed deeply enough to include the sinewy tissue in front of the pubic bones) and covered by an occlusive dressing.

During the act of severing the subpubic ligament the hip-bones ought to be well supported, lest separation take place too suddenly. If this is neglected, the pubic bones will suddenly be thrown widely apart with an audible sound, and laceration of adjoining structures may easily take place. A catheter in the bladder will be useful in keeping it out of harm's way. I am very much inclined to think that the omission of these very important precautions has been the cause of a number of accidents so far reported.

As far as suturing the bones with silver wire is concerned, as recommended by some surgeons, I think it objectionable on the ground that in case of a possible future operation these very sutures would increase the difficulty of opening the joint; besides, it seems to be the consensus of the majority of operators that union will readily take place without any bone-suturing. To facilitate this union a tight bandage may be passed around the hips, the limbs brought together and the patient placed on a so-called trough-bed, as suggested by Dr. Robert L. Dickinson, of the Long Island College Hospital, and described in the *Medical Record*, 1893, vol. lxiv, No. 22. A long and moderately hard pillow is placed on each side of the mattress, over which is spread a rubber sheet and other sheets above it. On this trough the patient will lie in such a fashion that the weight of the lower part of the trunk and thighs is received on the iliac crests and trochanters. The legs are rotated inward, the knees pressed together, and the tendency to separation of the symphysis is overcome, as it occurs when the weight of the body is borne on the sacrum.[1]

The principle on which this simple device is planned is certainly excellent, although there is room for certain modifications in the arrangement of the practical details of the apparatus. Thus, I should suggest the use of wedge-shaped upholstered cushions with an inclination of about 45°, which could be fastened on a light wooden frame in such a fashion that they could not be shifted in a lateral direction by the weight of the patient, according to whose size the distance between the two sides should be regulated. In this way the patient could be lifted or entirely removed from the bed without causing the least motion in the pelvic joints.

Dickinson, in the article referred to, calls attention to the fact that in his case the peritoneum and bladder pouched into the wound, and proceeds to show at what stages of labor this complication was likely to occur. From a study of frozen sections of women who died late in pregnancy, and at different stages of labor, as given in *Braun's Atlas of Topographic Anatomy*, and in *Barbour's Atlas of the Anatomy of Labor*, we come to the following conclusions:

The structures found behind the joint will be:

(1) Before full dilatation and a certain degree of descent: The peritoneum and bladder in the cavum Retzii.

(2) After full dilatation and some descent: The lower part of the bladder and urethra firmly pressed against the joint.

(3) After delivery: The peritoneum and bladder.

The bloodvessels that are located behind the lower part of the symphysis in the cavum Retzii will be found beneath the arch during labor, and, with few exceptions, after delivery they are still in the same position.

The practical conclusion to be drawn from these anatomic facts is that we must expect to find the bladder and peritoneum behind the joint in all cases in which the conjugata vera is shortened, in consequence of which the head cannot engage in the pelvis, and in which full dilatation has not taken place, while in those cases in which the head has descended in the true pelvis, but cannot be born, owing to a contraction of the pelvic outlet, the peritoneum and upper part of the bladder are pushed above the symphysis, and only the lower portion of the latter with the urethra are in close apposition with it. It is evident that under these conditions there is greater danger of wounding any of these organs than in the first-mentioned cases, in which the peritoneum and bladder could be easily held out of harm's way with the finger. The clitoris may be lacerated by a sudden separation of the joint because of the attachment of its crura to the rami of the pubes and ischium, an accident that would be followed by troublesome hemorrhage, and, therefore, great care ought to be exercised to prevent the occurrence of this mishap.

I am unable to explain the presence of bloody urine, which has been observed in some instances after symphysiotymy, without advancing the theory that laceration of the mucous membrane of the deeper portion of the urethra may take place in consequence of violent stretching of this canal. If it were caused by an incised wound in the bladder, extravasation of urine in the pelvic tissues would naturally complicate the accident.

---

[1] There is a little room for the bed-pan to be slipped beneath the patient while the inward pressure still continues.

In order to illustrate the various ways in which the operation may be complicated I shall cite a few cases taken at random from the accessible literature:

In *Centralblatt für Gynäkologie*, 1893, No. 5, page 81, Krassowsky reports a case of symphysiotomy in a deutipara with a conjugate of eight centimeters, in which there was considerable hemorrhage from the cavernous body of the clitoris; the right iliac synchondrosis was heard to rupture; cystitis followed; there was slight mobility of the symphysis after recovery.

Smyly (*British Med. Journal*) reports a case in which the bones, separating rapidly, tore the soft parts beneath the urethra; the laceration was repaired with catgut; besides a bedsore a urinary fistula developed, which was cured by a second operation.

Kein (*Gazette de Gynécologie*, 1893, No. 16) reports a case in a multipara on the third day of labor, in which the pelvis was narrowed by fibroids of the sacrum and pubes. There was a purulent vaginal secretion. The patient made a good recovery although two abscesses formed at the ends of the incision.

Bidder (*Centralblatt für Gynäkologie*, 1893, No. 24) reports the case of a primipara, eighteen years old, in which a purulent discharge appeared. The left labium near the clitoris contained a broad tear, which was repaired with silk. Endometritis and a stitch-hole abscess delayed recovery. There was a furrow visible on the surface, as the bones had not entirely united. After five weeks the patient was discharged from the maternity hospital.

In a case reported by Maygrier, in the same journal, symphysiotomy was done for dystocia caused by a periosteal tumor on the left side of the symphysis. After prolapse of the cord and one arm, embryotomy was performed; the anterior vaginal wall was torn to the extent of five centimeters. On the second day the patient suddenly died from a clot in the right pulmonary artery; the symphysis was separated only 2.5 centimeters.

Tellier reports a case in a primipara, twenty-seven years old, in which the perineum, bladder, and urethra were torn, and the patient died from shock two hours later; the child survived.

Lepage (*Centralblatt für Gynäkologie*, 1893, No, 20) performed symphysiotomy for dystocia, caused by a round tumor on the left side of the pelvis, with a favorable result.

Wertheim, in the same journal, reports a case in which the patient died on the eleventh day of sepsis, due to infection previous to operation. There was considerable odor to the liquor amnii.

Coe (*Medical Record*, 1893, No. 1172) reports a case in a patient with a contracted pelvis and deficient in mental development. She recovered from the operation, but died two months later demented. Union between the bones was firm.

In consideration of the fact that dementia has sometimes followed an otherwise normal delivery, this one case can hardly justify the conclusion that the operation was the cause of the mental disturbance. It is true that after some cases of ovariotomy dementia has also been observed; but the effect of the removal of the ovaries upon the whole organism must necessarily be so entirely different from that of a simple and only temporary separation of the pubic bones that a comparison of the two operations in this respect is absolutely inadmissible.

The case that I now report is one of those rare exceptions in which the difficulty in labor will be met with toward the pelvic outlet, owing to a contraction of the transverse diameter.

The patient was a primipara, twenty-eight years of age, below the medium size (a Jewess, of German ancestry, born in Rochester, New York, now living in San Francisco). I was called to see her in consultation with Dr. Dodel on the afternoon of January 13, 1893. She had been in labor for about twenty-four hours, and was showing signs of exhaustion. The fetal heart-sounds were strong and regular. The head presented in the first position, and had descended deeply in the cavity of the pelvis. The examining finger could reach the anterior fontanel. The uterine contractions had almost entirely ceased, in spite of the usual remedies employed for bringing on labor-pains.

Owing to the weakened condition of the mother, it was deemed advisable to terminate labor by the use of the forceps. After the patient had been anesthetized I introduced the hand in order to apply the forceps, but found it extremely difficult to gain an entrance into the vagina. It was only after considerable effort that I finally succeeded in forcing my hand inside, but by doing so I found that I had not made much progress, for it was impossible to introduce even the first branch of the instrument, and at the same time I felt in a painful way how the descending rami of the pubic bones impinged upon my hand, holding it in a vise-like grip, and forbidding any freedom of motion. The truth of the old saying, "Manus est optimus pelvimeter," never struck me so forcibly before, when it became clear to me that I had to deal with a funnel-shaped pelvis. On withdrawing the hand I found that in my efforts to gain an entrance into the vagina I had caused a laceration at the introitus vaginæ and ruptured the perineum, which gave rise to considerable hemorrhage.

After packing with iodoform-gauze in order temporarily to check the hemorrhage, I proceeded to perform symphysiotomy in full accord with the opinion of my colleague.

In the absence of sufficient assistance it was deemed advisable to make use of a leg-holder, the patient being brought to the edge of the bed and placed in the lithotomy-position. The joint was opened according to the subcutaneous method, and the bones separated suddenly and with an audible sound as soon as discission was complete. It was necessary to use the forceps to effect delivery, and a considerable degree of traction was necessary to accomplish this end, owing to incomplete dilatation and rigidity of the cervix. The distance between the pubic bones during extraction I estimated to be about five centimeters. The silkworm-gut sutures used to close the wound were passed as close to the bones as possible, and a long roller-bandage, about four inches wide, was used to bring together the hip-bones, over which was applied on the next day an elastic rubber bandage. The wounds in the vaginal wall and perineum had also been repaired with silkworm-gut.

The patient passed bloody urine on the following two days, and later it became purulent; but after washing the bladder several times with a 1 per cent. solution of silver nitrate this soon ceased. She made an uneventful recovery, and in spite of a narrow furrow which is palpable over the symphysis, her walk is perfect. She left the bed four weeks after the operation. The child is strong and healthy.

In this case the operation had to be done under the most unfavorable conditions imaginable. The room was dark, and a small oil-lamp, together with a couple of candles, without candlesticks, were all that was available for illumination. The bed was so dilapidated that it broke down before the work was done and the child had to be extracted, the mattress on which the patient rested being on the floor. Of assistants I had just one—my son, a medical student in his second year. Dr. Dodel had charge of the anesthesia. It was only with difficulty that we could obtain the necessary amount of hot water for preparing our antiseptic solutions and so on.

This case has taught me the lesson that it is not safe to depend on the use of a leg-holder alone when doing symphysiotomy, but that at least one more assistant ought to be secured, whose part it would be to prevent a sudden separation of the pubic bones by making a certain degree of counter-pressure against both hip-bones, for I feel satisfied that the hematuria was caused by some sort of laceration taking place in the deeper portion of the urethra, or the lower part of the bladder, in consequence of this sudden separation.

In the absence of a pelvimeter there was no possibility of ascertaining in figures the length of the different pelvic diameters which are of obstetric interest.

Since the convalescence of the patient I have taken some measurements with the following results:

Conjugate vera, 10.8 centimeters.

Transverse diameter of outlet, 9 centimeters.

Antero-posterior of outlet, 11 centimeters.

The length of the conjugata vera is of no interest in this case except to show that it came very near the norm. The principal difficulty was caused by the shortness of the transverse diameter of the pelvic outlet. For securing this measurement Breisky's method was used, as well as Schrœder's, both measurements giving the same results.

In view of the fact that a narrow furrow was palpable over the whole length of the symphysis the conclusion is inevitable that a permanent increase in this diameter must have resulted from the operation. I am inclined to think that originally it was not much above 8.5 centimeters.

The final conclusions to be formulated from this paper would be that:

1. Symphysiotomy is indicated in flat pelves with a conjugate of from 67 to 88 mm.; in funnel-shaped pelves with a transverse diameter of pelvic outlet of 88 mm. or less; in cases of dystocia caused by tumors in the pelvic cavity; in cases of abnormal size of the fetus, but with normal pelvis; and that it finds a useful application in the removal of tumors of the bladder and pelvis, provided the age of the patient does not present a contra-indication; but in those cases in which prophylactic podalic version is still possible, this ought to be preferred to symphysiotomy, even in a pelvis with a conjugate of not more than 8 centimeters.

2. It should replace Cesarean section and embryotomy whenever these are indicated within the lower limit of contraction.

3. The results are favorable to mother and child.

4. The operation is easily performed. Besides an obstetric outfit all that is needed is a surgical pocket-case.

5. It can very well be done outside of maternity hospitals. The after-treatment offers some difficulties in private houses.

6. Although comparatively safe, the operation may, in the hands of the inexperienced, be followed by serious accidents; it therefore ought not to be done lightly without an imperative indication.

7. As it is an operation of urgency, like tracheotomy, every physician should be able and ready to perform it.

THE SURGICAL TREATMENT OF INGUINAL HERNIA.[1]

By HENRY O. MARCY, M.D.,
OF BOSTON, MASS.

In order that we may the better understand the varying conditions presented in operative cases of inguinal hernia, I shall first ask you to review with me the anatomic structures in their normal development. The anatomic plan of construction of the parts in the transmission of the spermatic cord and vessels through the abdominal wall is by a line so oblique that the intra-abdominal pressure is normally placed at or near a right angle to the axis of the inguinal canal. However singular it may seem, I do not remember to have found a single reference made to this anatomic disposition of the structures in its possible application to the cure of hernia. This is, very probably, because the restoration of the parts to their normal anatomic relationship was impossible without the use of buried sutures.

In the upright position the weight of the abdominal contents is deflected forward by the promontory of the sacrum, in a way to lessen greatly the gravity-pressure upon the pelvic organs. The recti muscles form a strong supporting column with their basic anterior pubic attachment. Muscular strain, brought to bear with any degree of violence upon the abdominal wall, causes a deflection of the compression-force in nearly equal degree from the promontory of the sacrum, upon either side, to the aponeurotic attachment of the muscles to the pelvic bones. Thus it would seem that when the normal conditions obtain, this force must ever act in right lines to the inguinal canals. Were it not for this it would be difficult to understand why the normal condition of man, as an upright animal, should not be that of a hernial protrusion of the abdominal contents along the lines of a necessarily open inguinal canal.

---

[1] Read before the Annual Meeting of the New York State Medical Association, 1894.

Perhaps we are more deeply indebted to Sir Astley Cooper than to any other for pointing out this remarkable provision of nature for the production and maintenance of this normal equilibrium of function and retaining force. He demonstrated that the transversalis fascia lying immediately beneath the peritoneum was normally so reinforced and strengthened as to form a strong posterior wall to the inguinal canal, and that it also, by the dissemination of its fibers about the cord, made a firm boundary to the internal ring, thus producing a fixation-point of definite character for the exit of the cord from the abdominal cavity.

Tracing the developmental forces during the late fetal period, we note the interesting and remarkable process of extrusion of the testicle from the abdomen, and the carrying with it of the peritoneal covering investing its vessels and vas deferens, making up the so-called spermatic cord. Normally, the peritoneum is so closed in about these structures at its exit from the abdomen that only by pulling upon the cord do we note the slight depression upon the peritoneal surface which lines the abdomen at this point. Not seldom, however, in individuals who are not subjects of hernia, the transversalis fascia about the internal ring is more open than normally, and the peritoneum, shutting in about it, is left in a considerable depression. Indeed, this condition exists so frequently that it has received the name of the infundibular process of the peritoneum. These are the conditions which are very commonly present as predisposing factors in all subjects of hernia.

Remembering the disposition of the intra-abdominal pressure as already noted, it is easy to understand that when this condition exists there is brought to bear upon the depression, in every movement of the body, a more or less powerful hydrostatic pressure upon this weak point, acting as a wedge, until at last the equilibrium of the forces is so disturbed that, little by little, the parts yield, the internal ring enlarges, the inguinal canal is by this much shortened, until by some extra force the external structures suddenly give way and the man finds himself ruptured—that is, a portion of the abdominal contents has become displaced through an abdominal opening.

I have presumed to occupy thus much of your attention in the consideration of the normal anatomic relations and functions of the parts involved in inguinal hernia, because this knowledge is especially important to the surgeon who, by operative interference, expects to secure a permanent restoration of the weakened structures, rather than to qualify himself only for the relief and restoration of the abdominal organs in strangulation.

The time at my disposal prevents a careful analytic discussion of the varying conditions that may be met with in the cases presenting themselves for operation, but assuming that we may favorably consider the subject of a hernia, who is otherwise healthy, a proper applicant for surgical relief, we shall take first into consideration those cases coming to us in infancy and childhood, the larger number of which will be of the congenital variety. Here it is well to remember that we have no hernial sac proper with which to deal; in other words, the scrotal pouch of the peritoneum containing the testicle is in direct continuation, as an open canal, with the abdominal cavity. We find usually that the opening in the transversalis fascia is very large, and the surgical procedures are not unlike those recommended for the restoration of the obliquity of the inguinal canal in cases of acquired hernia, after the peritoneal sac containing the hernial contents has been sutured and resected.

The dissection is commenced at a point a little above the internal ring, and is carried down sufficiently far on a line with the cord to expose clearly the internal ring. The structures over the cord are divided so that the latter can be elevated and clearly expose the border of the internal ring and the posterior wall of the cord. Either by finger, or some convenient instrument, an assistant holds the cord, freed from its attachments, toward the middle line with sufficient tension to define clearly its relationship with the deeper structures. This is done in order that a clear field may be had for the application of the sutures for the reinforcement and reconstruction of the posterior wall of the canal. For the accomplishment of this it is absolutely essential to use sutures that are buried in the structures, and are, as a consequence, beyond the power of the surgeon for subsequent removal. By general consensus of opinion, silk, although it may be used as a buried suture, is not considered applicable for this purpose. For somewhat similar reasons silkworm-gut proves unsatisfactory, because both of these materials, not being absorbed, are liable as sutures to prove irritants, and, in the subsequent muscular strain of the parts, are thrown off as foreign bodies. Good chromicized sterile catgut may serve as a trustworthy material for suture, but for a considerable variety of reasons, which cannot be referred to here, it has proved far inferior as a buried suture to tendon, preferably that from the tail of the kangaroo.

The way in which the suture is applied for the reinforcement of the parts, and the structures to be included for this purpose, vary considerably. I have felt for a long time that a double continuous suture is to be preferred, and for this reason devised the method of sewing in which the suture is applied by the use of a curved needle with an eye near the point. The first stitch is taken by entering the point of the needle through the lower border of the attachment of the conjoined tendon and the inferior posterior border of Poupart's ligament. The needle is unthreaded, the suture centered and tied in a half-knot, the needle rethreaded with the opposite end of the suture and withdrawn through the opening made at its entrance. Continuous sutures to the number of three or four are applied in this way until the last stitch closes firmly the inferior border of the internal ring quite upon the cord at its exit from the abdomen. The last stitch taken, the suture is tied upon the side and the ends cut short. It must ever be remembered that the object of the suturing is to hold the structures in even approximation without tension, and the chief danger from suturing lies in an *undue constriction* of the tissues. When properly applied, it will be observed that the transversalis fascia has been reinforced by the attachment of the posterior border of Poupart's ligament to the posterior border of the conjoined tendon, thus forming a new strong wall of the inguinal canal. Into this slit the cord is replaced and the external structures are joined so as to make a firm, strong closure of the parts over the cord. For this purpose buried tendon-sutures are equally desirable. These may be applied, as already described, by a line of double continuous suturing, re-forming the external ring by bringing together the outer border of Poupart's ligament and the conjoined tendon.

For one who does not possess a needle such as that described, the single continuous suture, applied with a curved Hagedorn needle, answers very well. The first stitch should be fixed by a reef-knot, and the needle is then inserted at a more or less considerable distance from the line of the division, but taken deeply through the aponeurotic structure on a line *parallel* to the incision. The needle is then introduced exactly opposite its point of former emergence through the structures upon the other side of the parts to be approximated, and in this way one stitch follows another to the end of the wound. It will be noted that tension upon the suture evenly intrafolds the edges, the suture itself, buried in the tissues, crossing the line of division only at right angles. In this way the line of union is very much deepened, and may be easily more than doubled, greatly reinforcing the structures adjacent to the canal. Another layer of sutures, similarly applied, approximates the soft parts, and a line of running sutures, taken through the deep layer of the skin only, closes the wound. This is dried and sealed with iodoform-collodion. No subsequent dressing or bandage is applied. The tunica vaginalis testis is thus re-formed, and the peritoneum closed securely about the internal ring so as to leave no depression.

The opposite extreme, the old large hernia in the adult, requires little deviation from the method described, except that the sac is first dissected free from its attachments, opened, to be assured of its contents—which may be disposed of as judged best, and then, quite within the ring, the sac is freed from adhesions and made tense by an assistant. The base is sewed across with a double continuous suture in a line with the axis of the wound, and the sac is resected. The retraction should be quite sufficient to place it out of the way in the subsequent steps of the operation, which are those that have been described for infantile hernia.

For teaching purposes I like best the large old scrotal herniæ, in which trusses have proved inadequate for the retention of the abdominal contents, since the various steps of the operation can be made more easily apparent.

Inguinal hernia in the male has ever been considered the most difficult of treatment, since the opening in the abdomen must be closed in a way to permit the passage of important structures, which, at the best, can add nothing to the support of the parts. In the seventeenth century it was found an easy matter to cure inguinal hernia by first removing the cord, and great numbers of hernia-patients were deliberately castrated as a means to this end. More recently, before an open dissection-wound was considered permissible, a great variety of ingenious subcutaneous devices were applied for the purpose of cure, but were usually followed by failure. Since it has been possible to make and maintain wounds in a non-infectious condition the advance toward the permanent cure of hernia has been rapid, until, in very recent years, new methods of cure are being constantly brought before the profession. However great in variety of detail, they must all be based upon a very few fundamental principles, and, in order the better to emphasize these, I have occupied so much time with the consideration of the normal anatomy of the parts involved.

Of course, the *ideal* method is to restore the parts to the normal standard of construction ; pathologic deformed structures having been removed, *e. g.*, sac and contents. To do this, it is necessary to restore the obliquity of the inguinal canal by the reconstruction of the internal ring, and to reinforce the posterior wall. To effect this, a free dissection must be made, and buried sutures must be used. It was for this very purpose, so far as the records of surgery show, that buried sutures were first employed. I had just returned from Europe and the instruction of Mr. Lister, and was familiar with the use of the buried animal ligature for the closure of arteries. It seemed a proper application of the principle that sutures might in like manner and with like result be buried in the tissues. For this purpose I first used catgut in 1870, which, prepared in various ways, I continued to use until 1880, when I made an extended search for some better material of like histologic structure. These investigations resulted in finding the exceptionally valuable tendon suture-material from the tail of the kangaroo. I demonstrated, histologically, that aseptic connective tissue, buried in healthy animals, is at first surrounded by leukocytes, that the foreign material is invaded by them, that, little by little, new connective tissue of a permanent character replaces the implanted suture. Since then I have used tendon-sutures almost exclusively.

It has been demonstrated that other material may be used for sutures, and that it may be applied in quite a variety of ways. These variations in detail and technique have been called *methods*, and have been presented under different names, *e. g.*, that of Bassini of Italy, perhaps the best known. He uses an over-and-over continuous catgut suture, and places the coapted conjoined tendon and Poupart's ligament behind the cord. Potempski thinks it important to carry the internal ring to a higher point than normal. Fowler modifies this procedure by carrying the internal ring nearer to the median line, while Halsted thinks it wise to cut away a part of the veins in order to reduce the size of the cord, and, as a consequence, the size of the canal. It remains to be seen how much additional value comes from these modifications; if the liability of the return of the hernia is lessened, and if, by such extreme measures, the function of the reproductive organs is not impaired.

It is ever honorable and pleasant to associate the name of the individual with the contribution of real merit which he makes as an addition to the store of the world's knowledge. However, little by little, names given to operations after the individual by whom they were established sink into forgetfulness, and wisely so, that they may not overburden our literature; but the plain underlying principles must ever be kept in mind as the true foundation of all present and future improvement.

For the cure of hernia by a restoration of the structures to their normal anatomic standard and relationship—and is it probable we shall find a better?—I introduced the use of buried animal sutures, which has been since widened in its application to all aseptic wounds. I demonstrated that a new oblique inguinal canal could be safely made and maintained; that the entire wound could be closed by buried sutures and sealed with collodion without drainage; and that primary repair ensued without pain or edema. I also showed that 90 per cent. of my cases remained permanently cured; all this before any of the modifications referred to were published. Whatever may be their advantages remains for others to determine. I know that the reinforcement of the structures posterior to the canal is ample, if the inner border of the conjoined tendon and Poupart's ligament is joined to the relaxed, but strongly developed, transversalis fascia. This fascia is very much thicker in this region, as was pointed out by Sir Astley Cooper, and for a long time, on this account, called the *fascia Cooperi*.[1] Often its intrafolding is all that is requisite to give a firm and durable support.

The introduction of animal sutures, aseptically buried in the tissues for a very great variety of purposes, especially the possibility by their use of the closure of the peritoneum and the reconstruction of the inguinal canal for the cure of hernia, I offer as a contribution to American surgery. It is with much satisfaction that I find that these surgical measures are now so very generally adopted throughout the civilized world.

Before closing, there are a number of practical considerations which are offered for discussion. Of these perhaps the first in importance is, When shall we operate? At present I suppose there are few surgeons who would dissent from the proposition that, in strangulated cases, always at the first moment practicable. Any attempt at reduction should be made with exceeding care, and after such efforts have failed immediate operation must be advised.

Operative measures for the relief of strangulated hernia vary essentially from those earlier advised in that the dissection is a free one and is always under visual guidance; that blind surgery is bad surgery can nowhere receive greater emphasis than in the operation for the relief of strangulated hernia.

The hernial contents having been disposed of, few operators would now consider their work complete without closing the structures in some of the ways advised for the purpose of permanent cure. The earlier attempts made to utilize the sac for the reinforcement of the opening—as, for example, the Macewen method—are now very generally abandoned, since the reinforcement of the structures posterior to the cord, in a very much more satisfactory manner, closes the weakened parts.

---

[1] Muscular fibers may be traced behind the cord, as if the canal entered through a slit in the transversalis muscle. "The transversalis muscle arises from Poupart's ligament and passes around the spermatic cord at the internal ring, so that the fibers of this muscle appear behind as well as before the spermatic cord, and thus the inguinal canal is rendered a muscular canal. This is a most important provision in preventing hernia, and when hernia exists, is often the cause and seat of stricture."—*Sir Astley Cooper.*

Hernia in children. Until a moderately late period nearly all this class of little sufferers have been relegated to the instrument-makers. However, every surgeon is painfully familiar with the fact that it is exceptionally difficult to secure the proper wearing of a retention-apparatus, and that, at the best, the cure of hernia by these means is tedious, painful, and unsatisfactory. The earlier attempts at cure of hernia by dissection and suturing were in large measure unsatisfactory, because of the use of the interrupted suture, which had to be removed, and the extreme difficulty of keeping the wound aseptic on account of the application of the drainage-tube. It is painful to recall the punishment of the little sufferers because of the multiple aseptic dressings, sometimes held in place even by plaster bandages. With all the care possible, the great majority of the wounds became infected, dangerous, and far from satisfactory in results.

The closure of the parts, as already described, with the seal of collodion, renders further infection impossible, and primary union supervenes without pain or edema, resulting almost invariably in permanent cure. It is pitiable in the extreme to send a boy, rich or poor, into the race of life suffering from hernia, and handicapped with the necessary wearing of a truss.

Hernia in adults. It may be considered an open question if active, vigorous men who are sufferers from small herniæ, easily retained by a truss, should be subjected to a surgical operation. The expense incident thereto, the loss of a number of weeks during which they must abstain from business, are set over against the inconvenience of wearing an instrument, the probability of the hernia continuing to grow more troublesome and pronounced, and the ever-possible danger of strangulation. For my own part, I think the balance of account is usually in favor of operation, and I cannot question that the profession is each year becoming more and more of this opinion.

Hernia in the aged. As at other periods, the problem must always be considered as one of individual character. This becomes more especially so in the later years of life. Assuming that the hernial subject is free from organic disease, age *per se* weighs far less seriously as an adverse consideration in aseptic surgery than was earlier supposed. Primary repair of the tissues is almost certain to ensue with remarkably little constitutional disturbance. The contrast between septic and aseptic wounds is much more marked in advanced life, and aseptic surgery wins, perhaps, its most brilliant victories in the operative wounds upon the aged. I have operated upon a very considerable number of patients between seventy and eighty, under the most unpromising conditions, and even upon several between eighty and eighty-five, and in each instance with seeming easy cure.

In illustration, I cite a recent interesting case, and exhibit the specimens.

Mr. M., aged seventy-one years, a hard drinker, had for a very long period suffered from an old irreducible scrotal hernia of the right side. It had recently enlarged until the tumor extended quite one-third to the knee and measured about eighteen inches in circumference. An inconsiderate truss-vender had applied a strong-spring instrument upon the neck of the sac, and such inflammation had supervened that it was thought dangerous to permit delay in operation. The tissues were ecchymosed, and the sac was found to contain about a pint and a half of straw-colored serum and a fatty omental tumor the size of an adult fist, with basic attachments. The omentum was sewed across, resected, and returned within the abdomen. Several pints of ascitic fluid escaped from the canal, which readily admitted three fingers. The sac was dissected, sutured, and removed. The wound was closed, as already advised, and sealed. The man was found to have chronic nephritis, with albumin and casts in the urine, and jaundiced to a limited extent. This condition grew steadily more marked, and twenty-six days after the operation death took place.

The autopsy showed an interstitial hepatitis, the liver being reduced to half the normal size, with advanced disease of both kidneys. The union of the abdominal wound was primal, and I take pleasure in inviting your critical inspection of the specimens. The omental stump is smooth and the cut ends of the tendon-suture are apparently unchanged. The peritoneum at the base of the sac is firm and glistening, showing only the slight wavy line of union. The reconstructed abdominal wall is noteworthily deep and strong, nearly one-third thicker than upon the opposite side, owing to the intrafolding of the tissues. The skin-wound is marked only by a linear cicatrix. The fatty tumor of the omentum is exceptional, seeming on section to bear no trace of intrafolded compressed omentum, of which it is doubtless composed ; the thick, firm, leathery sac can even now be dilated to the size of a baby's head.

It will be noted that even in this aged man, dying from a complication of chronic diseases, the repair-processes, under aseptic conditions, went on uninterruptedly, precisely as in a young, vigorous adult.

Multiple operations. Individuals with hernia, suffering from various other conditions demanding surgical interference, may, as a rule, be safely operated on at the same time. It is usually advisable to operate upon both sides at once when the hernia is double, the repair-processes going on equally well, with a marked saving of time and confinement. I have even operated upon double inguinal and umbilical herniæ at the same time, with an equally easy convalescence and recovery. Multiple wounds, if aseptic, demand little more from the vital powers during the process of repair, and there is much positive gain to the patient in time, expense, and confinement. Multiple operations have long been almost of daily occurrence in my surgical practice.

If operative measures are so generally advised for this disablement, it must be that the surgical procedures are attended with very little risk of life. Upon this subject the testimony is ample, and perhaps no other operation demonstrates more clearly the differences of result obtained under modern aseptic technique. Nearly twenty-five years ago, when I first commenced operation for the cure of hernia, it required persuasion to secure the presence even of physicians, because of the responsibility incident to personal attendance. So general was the belief—and, unfortunately, on altogether too good evidence—that an open dissection-wound made for the cure of hernia was always dangerous, that operation was not advised except in cases of strangulation.

In my recent work upon hernia,[1] I have collated over three-thousand operative cases of hernia by various aseptic surgeons, who report less than one per cent. of deaths, and these explained by conditions in which the wound itself had no part. In my entire experience of over two-hundred cases I have never seen a patient approach the danger-line following operation when the intestines were not involved.

He who is master of aseptic conditions may safely operate for the cure of hernia, if he is thoroughly conversant with the anatomy of the structures. *Aseptic sutures, aseptically applied in aseptic wounds*, and aseptically maintained. This is the *sine qua non*, or failure will ensue; otherwise buried sutures are not to be commended in any wound, and must even be a source of danger.

In how large a percentage of cases may we expect permanent cure?

Upon this question there has been and still is a great variety of opinion, based upon the results, of course, obtained from the various methods of operation in use. We can well understand the opinion as given by Dr. Bull, of New York, that relapses are the rule rather than the exception, when we remember that the results of the operations that came under his observation were due to methods that failed to secure the restoration of the obliquity of the canal, or the reinforcement of the deep structures. The removal of the sac and the suturing of Poupart's ligament to the conjoined tendon, without the re-formation of the inguinal canal, necessarily left a large funicular opening in the abdominal wall, the very end of which only was closed at the external ring. Under such conditions, it is usually only a question of time before the hernia reappears.

In 1893 I read a paper before the American Medical Association, in which I gave an analysis of one-hundred-and-thirty-three cases that I had been able to keep under observation; of these there were six recurrent herniæ, four of which I have since operated upon. About one-third of this number had been under observation for ten years and more.

Did time permit, I would gladly quote from the experience of some of the recent operators, of whom, perhaps, none is more enthusiastic at the present than Dr. Bull himself and Dr. Coley, of your city.[1]

Corroboration of the principles and position that I have advocated so long is now ample, and there is little question that the more serious sufferers in the great army of truss-wearing individuals will early receive from the surgical profession easy and safe curative measures. In this field aseptic surgery has won one of the most brilliant victories of the present revolutionary period.

A NEW METHOD OF PEDICLE-LIGATION IN ABDOMINAL SURGERY.

By SCHUYLER C. GRAVES, M.D.,
OF GRAND RAPIDS, MICH.,
VISITING SURGEON TO THE U. B. A. HOSPITAL, AND SURGEON TO THE CHILDREN'S HOME, GRAND RAPIDS, MICH.

The death of a patient from hemorrhage due to faulty pedicle-deligation during the course of an abdominal operation is a catastrophe sufficient to cause the cheeks of any surgeon to pale. When all else in the technique has been perfect; when asepsis has had full sway; when there has been no particular bleeding, no shock, no complication; when the danger of subsequent peritonitis is practically *nil*, and everything bespeaks a favorable outcome, the death of a patient from the slipping of a thread is an awful calamity, and any method by which the possibilities of such a *denouement* may be narrowed is a matter of vital interest to both patient and surgeon.

---

[1] The Anatomy and Surgical Treatment of Hernia. Illustrated. Quarto. D. Appleton & Co. 1892.

[1] From a recent letter by Dr. William B. Coley of New York I quote: "I have used kangaroo-tendon in 170 of my 183 cases of hernia, and have never had any trouble from it; and I believe my success was largely due to using it as a buried suture-material. No other results, here or abroad (except, perhaps, your own), show such a percentage of immediate or final cures. Of my 140 cases where the cord was transplanted I have had but one relapse—137 cases traced. In 170 cases where kangaroo-tendon was used, suppuration occurred only four times—and then superficial, outside the layer-sutures of tendon."

It is my purpose to put on record, for the use of the profession, a new method of applying a pedicle-ligature in abdominal surgery, by which the same not only *will not* but simply *cannot* slip.

The ligature has been employed in actual practice, with perfect satisfaction and ease of application, and has been exhibited to the members of the Grand Rapids Academy of Medicine at a recent meeting of that body.

There are four sources of danger from intermediary hemorrhage in the application of a pedicle-ligature: 1. The employment of the wrong knot. 2. The lack of sufficient force in tying the loop or loops. 3. The application of apparently sufficient force upon a pedicle while held in a state of tension. 4. A defective method of application.

1. No surgeon to-day needs to be told that the sailor-knot (also known as the reef, or square, or unslipable knot) is the one to be employed whenever even an isolated artery is to be tied. Comment on this point is unnecessary.

2. The lack of sufficient force in the tying of a ligature-loop is a real danger that should be carefully guarded against. If thought best, when a consideration of this point is under discussion, the pedicle can be ligated in sections sufficiently small to insure the operator's ability to compress adequately the included tissues.

3. Deaths have occurred from pedicle-hemorrhage after surgeons have used all the force they deemed necessary; but such force having been applied to the pedicle while rendered rigid by too great traction, the result, after the withdrawal of this traction, has been the same as when too little force has been exerted upon a lax pedicle, viz., the liberation of vessels, with the escape of blood.

4. The method heretofore employed in the application of pedicle-ligatures has been faulty in that it has always rendered possible a subsequent intermediary hemorrhage as the result of the slipping of a loop.

Even the Staffordshire knot, which was said to be perfect, has slipped, and thus permitted hemorrhage to occur.

In my opinion the Staffordshire method is vastly inferior to the one ordinarily used in this country, viz., central transfixion, linking, and tying both ways, as much more power can be employed in the latter than in the former. Of course, I am not discussing ligature-material in this contribution.

Geometrically speaking, a line (in this instance a diameter) is determined by two points, and, therefore, no looped ligature, single, double, or of the chain-variety, is safe, which is not fixed at two opposite points on the periphery of each loop, or, to be more explicit, at opposite extremities of their long diameters.

It can be said that such a condition obtains in the Staffordshire ligature, for such is, indeed, the case; but the weak point of that ligature in this connection is the fact that, in securing the two fixed points on the periphery of the main loop, two subordinate loops are made, the lateral diameters of which are almost certain to be longer than the opposite diameter of the main loop. Those familiar with the Staffordshire method will comprehend the force of this statement. The subordinate loops of this ligature are just as dangerous as the loops fashioned after the American plan, if not more so.

It is not my belief that the so-called American ligature is particularly unsafe. It is not. Deaths therefrom are rare. But it is certainly dangerous enough to warrant improvement, if improvement be possible. That it is possible I leave the reader to judge.

The old method is strong in this respect: that the ligature can never slip entirely away from the pedicle, for it has a fixed point at the center of the same; and this can also be said of the Staffordshire ligature, for I am now discussing the ordinary, double-looped ligature as described; neither can it slip when the distance from the loop to the section is greater than, or even the same length as, the diameter of the loop. These considerations, however, could have no weight with a single-looped ligature, and they are not simple enough, not accurate enough, for universal use. The security of a pedicle-ligature should not depend upon the distance, long or short, from the planes of its loops to the point of section.

FIG. 1.

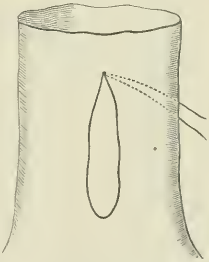

FIG. 2.

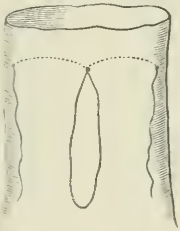

The accompanying drawings are self-explanatory. The loops, it will be seen, are fixed by passage through the substance of the pedicle at points on opposite ends of their long diameters, viz., in the center and circumference of the pedicle.

Any bleeding from the transfixions, and some does occur, may be disregarded, for all vessels of respectable size are included in the loops, or it can be readily checked by throwing a loop from one of the remaining ligature-threads around the entire pedicle and tying the same, as per drawings.

FIG. 3.

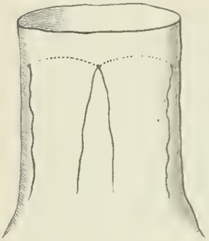

FIG. 4.

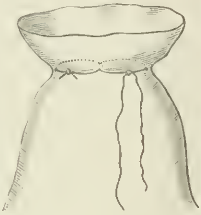

FIG. 5.

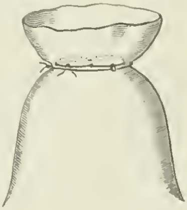

FIG. 6.

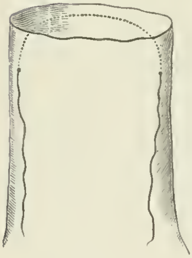

FIG. 7.

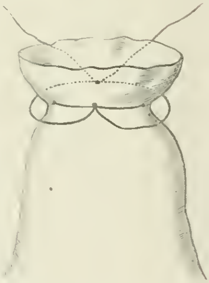


This long loop would, of course, have only *one* fixed point, and, therefore, might possibly slip; but such an accident is not at all likely to occur—not as likely as with the loops of the old ligature—because the thread lies in natural grooves rendered possible by the traction of the primary loops at the points of peripheral penetration, and even if slipping *should* occur, the danger would be practically nothing, on account of the insignificant size of the involved vessels.

Finally, if an operator, when he has occasion to deal with the pedicle of any variety of tumor, or with the bases of degenerated or suppurative tubo-ovarian masses, will, *first*, make use of the reef-knot in connection with his ligature; *second*, employ sufficient compressive force in his application of the same; *third*, be sure that the tissues to be ligated are lax when the knot is drawn, and, *fourth*, apply the method here described, he will, in my opinion, be doing all that it is possible for man to do in the prevention of one of the saddest accidents incident to the practice of surgery.

The principle that underlies this new method, viz., that of peripheral fixation, is applicable in different ways. For instance, when a pedicle to be secured is slender or composed of soft tissues which are easily compressible and not too bulky, as is often the case, especially in the slighter forms of tubal and ovarian disease, there is no need of central transfixion. If the ligature-ends be simply drawn through the two peripheral points—opposite each other—and a single loop thus made, the ligature cannot slip. The ends of the ligature may then be passed around the entire pedicle as ligated and tied, to prevent the puncture-point bleeding, if thought advisable.

That central fixation is not necessary in the tying of slender pedicles is shown in Figs. 6 and 7. The abandonment of central transfixion in proper cases will save time.

I desire in this connection to acknowledge the artistic services of Dr. James Orton Edie, of this city, in the preparation of the drawings illustrative of the text.

CLINICAL LECTURE.

TUBERCULOUS LYMPHADENITIS—AN OLD DISLOCATION OF THE SHOULDER—SINUS FROM BULLET-WOUND OF THE HUMERUS.[1]

BY ROSWELL PARK, A.M., M.D.,
PROFESSOR OF SURGERY, UNIVERSITY OF BUFFALO.

TUBERCULOUS LYMPHADENITIS.

THIS patient is a girl of fourteen, who has a tumor in the axilla which is not rapidly growing, but which has certainly increased in size in spite of internal medication. You see in her features a pretty fair example of the second type of scrofulous diathesis. There is about them nothing attractive, no pearly sclerotic, no delicate skin, while the features are coarse. The child is a mouth-breather, the tonsils being moderately enlarged, but not enough so to account entirely for the mouth-breathing; neither is there obstruction of the nares. The person who breathes habitually through the mouth without any manifest mechanical interference with nose-breathing will almost invariably be found to be of low intelligence.

The history of the case is very meager; there is no account of an injury to the arm or hand; in fact I can offer no explanation why the axillary nodes should be affected rather than those of other parts of the body. While the nodes are steadily augmenting in size, they are not at all fixed in the surrounding tissue, as they would be if the trouble were malignant; nor is there evidence of carcinoma elsewhere in the body to which the nodular enlargement might be secondary. The girl presents the so-called scrofulous diathesis, which simply means that the soil is favorable for the development of tuberculosis. I can trace the involvement of the lymphatics under the pectoral muscles, extending up toward the neck; and it seems to me best, inasmuch as the child has not improved on appropriate medication addressed to the resorption of the enlargements, to remove the larger nodes and thus eliminate the greater part of the diseased process.

---

[1] Clinical Lecture delivered at the Buffalo General Hospital.

The operation is not particularly difficult, though the dissection is a little tedious. I have now removed a large lymph-node from the axilla, somewhat flattened, and the size of a hen's egg. Under the pectoral muscle I find another, disc-shaped, and about three centimeters in diameter. These, with several smaller nodes, I also remove. I shall close the wound without drainage, and apply an antiseptic dressing.

There is a lobular condition of the breasts that might be taken to indicate an extension of the tuberculous process; but I think it is physiologic, because the patient is at about the age of puberty, when the mammary gland enlarges, and is liable to present lobulations. In such a case as this I believe that the hypodermic use of tuberculin would be beneficial. Along with it I should advise the use of guaiacol and tonics.

AN OLD DISLOCATION OF THE SHOULDER.

This patient is a woman, of sixty-two, who fell down stairs sixteen weeks ago, and sustained an injury to the shoulder. She called a young physician who, according to the account given me, did not examine her shoulder very closely, but advised her to apply some liniment or lotion and rest her arm. This was done, but she did not recover the function of the arm, and she summoned a second physician, who discovered that the woman had a dislocation, and a day or two later he anesthetized her, and attempted to reduce it. The arm was bandaged after this attempt; but later it was found that the motion of the joint was not restored. This was eleven weeks ago. It is charitable and not unreasonable to suppose that the first physician reduced the dislocation with his first movement of the arm, so that he did not recognize the condition, and that later the head of the humerus again slipped out of place. It is admitted that he did not see the patient often. I mention the matter, not with any idea of blaming any one, but to impress upon you the necessity of making a careful examination in each case. The patient has been sent to the hospital for relief, but I have said to her and to her physician, that, although I shall make a reasonable effort to reduce the dislocation, I cannot promise that it will be successful; and that if reasonable efforts fail, rather than run any risk of breaking the bone, or rupturing large vessels, I will abandon the attempt and resect the head of the humerus, thus relieving her pain and allowing the arm to be moved. Theoretically it is possible to break the adhesions, but practically it is also possible to break other structures. Once I broke the surgical neck of the humerus in the attempt; but this accident occurred in an insane patient whose bones were more fragile than usual. It has happened in the experience of others that the axillary vein or artery has been ruptured, producing a hemorrhage calling for immediate amputation. So far as the interest of this patient is concerned, it is not justifiable to use much force. The veins and arteries have become more or less brittle from age, while the bones are weaker. The adhesions which have formed in a shoulder-joint sixteen weeks after dislocation are so firm as to render reduction often impossible. In attempting to break adhesions for any purpose in surgical practice, unless you succeed the result is an increase of the evil, because adhesions are composed of organized clot and inflammatory exudate; and when a band is torn, as many must be by active manipulation, hemorrhage occurs, and more exudate is thrown out, glueing the parts still more firmly together. However, in the present instance there is nothing to lose by the venture, for the slight mobility of the arm is of no practical benefit.

With the patient anesthetized and lying on her back, I cannot show you all the signs of dislocation. You will note, however, that the axis of the humerus does not point to the acromion, but internally. Again, beneath the coracoid process I cannot indent the tissues as could ordinarily be done, but I come upon a hard mass which moves when I rotate the arm, and is evidently the head of the humerus.

Dugas' test depends upon the fact that when the head of the humerus is dislocated, and the hand of the injured limb is placed on the opposite shoulder, the elbow cannot be made to touch the thorax. This is on account of the barrel-shape of the thorax. Normally, the upper end of the humerus is away from the thorax, and the lower end can touch it, whereas, in dislocation, the head of the humerus is practically in contact with the thorax, and the elbow cannot also be made to touch the ribs. This test I cannot well demonstrate at this late stage, on account of the adhesions.

I shall show you another test, which is made by driving a sterilized hat-pin into the head of the humerus through the soft parts. You can see the movement of the head of the pin when the humerus is moved.

The attempt at reduction includes, first, rather rude miscellaneous movements to loosen the head of the bone from the nest in which it now lies. I have not only to overcome the displacement of the humerus, but the glenoid cavity has been unoccupied for so many weeks that it has become partially obliterated.

Kelly, of Dublin, has devised a method of reduction that consists in seizing the wrist, wrapping the arm about the surgeon's body and attempting to turn around. This pulls on the arm while, with his disengaged hand, the surgeon tries to direct the head of the humerus into the glenoid fossa. This method is applicable to certain recent cases, but not to old cases. Kocher's method consists almost purely of manipulation, with the exertion of very little force. It consists in extensive outward rotation, followed by traction on the elbow, while the arm is circumducted toward the body with an extensive sweep. As the hand is brought down, the arm is rotated inward.

You have seen me perform these movements, and I now find that the head of the humerus is loose enough, and in that sense the dislocation has been reduced. There is, however, no fossa into which it can fit. I shall retain the head of the bone in as nearly as possible the normal position for a few days, and then, if there seems to be no prospect of its finding permanent lodgment, I shall advise its resection.

SINUS FROM BULLET-WOUND OF THE HUMERUS.

This patient consults me with regard to a sinus in the right arm and near the shoulder, due to a bullet-wound from a revolver fired at a distance of ten feet. The sinus has persisted for some ten years, during which time pieces of bone have been discharged. Not only does the patient complain of the annoyance of the constant discharge of pus, but of late he has suffered from a numbness in the forearm and "rheumatic pains" in the shoulder. There is no indication that we have a lesion of a definite nerve-trunk. The numbness shifts, and is quite diffuse, showing that no single branch of the brachial plexus is involved. Trouble of this sort is not uncommon in cases of necrosis of bone.

We have to deal with a compound injury of bone, not, however, a compound fracture. In order to trace the direction of the bullet, I have asked the man to show me how he stood when he was shot. He says that the arm was hanging at his side. On inserting a probe I come upon what feels like chalk; that is, carious bone. Just where the bullet is I cannot say. Surgically speaking, there is but one thing to do here; that is, cut down upon and expose the bone, scrape out the diseased area, and, incidentally, remove the bullet if we find it. I shall take no especial pains to find the bullet, for one of the lessons that modern military surgery has taught us is, that a bullet may lie perfectly harmless in the tissues. We have lost the old terror of a piece of lead which has perhaps been rendered aseptic by the heat developed by its rapid passage through the air, and is usually encapsulated in the inflammatory tissue which organizes about it. During our Civil War almost every bullet was sought for. Since then we have learned that it is better to leave the wound filled with clotted blood—the best sealing that it could have—than to churn up the clot with a probe, and further lacerate the tissues in the attempt to locate and extract the bullet. Even to-day nine-tenths of the men who use the probe to find a bullet will use a dirty one. The practical demonstration of the utility of modern surgical principles as applied to military surgery we owe mainly to Europeans. These principles were first put to a severe test in military practice in the Campaign of the Caucasus between Russia and Turkey, and were reported on by Dr. Reyher.

There are times when it is of advantage to know where a bullet has gone, especially when we have to deal with wounds of the skull and brain. It is of advantage to know whether in a bullet-wound of the abdomen the bowel has been perforated or not, but such facts can usually be determined without probing. Again, by studying the direction of the ball when it struck the body, by knowing the bones or sheets of fibrous tissue from which it may have been deflected, by noting what nerves have had their function interfered with, we can derive more information as to the location of the bullet than we can from the use of the probe. For military purposes the probe is generally useless, and often has been worse than useless. Even in this case, when there was nothing to be feared from the use of the probe, it has given me little information that I could not have learned from the history and the appearance of the sinus. The lesson that I wish you to learn from this case is that, if a bullet-wound is properly attended to in the beginning, there is little occasion for secondary interference. Providing the skin be clean, and your hands aseptic, the best treatment you can give a recent bullet-wound is to apply an antiseptic occlusive dressing, and let the wound alone, unless suppuration calls for interference later.

[Later, the bone was exposed, curetted, the sinus eradicated, and an antiseptic dressing applied.]

CLINICAL MEMORANDUM.

OVARIAN SARCOMA WITH ASCITES: OPERATION; RECOVERY.

BY CAPTAIN A. E. BRADLEY,
ASSISTANT SURGEON U. S. ARMY.

MRS. G. W. C., aged sixty-six years, was first seen in October, 1893. Living eighteen miles in the country, her husband informed me that I had better go prepared to tap, giving me a brief description of her condition. I found her sitting in her chair with an enormously distended abdomen; she had been unable to lie down for over two weeks, and was suffering much distress from embarrassment of respiration. I succeeded in obtaining a specimen of her urine, which was found to be normal. There existed a marked degree of gastric distress and uneasiness, with eructations; the tongue was heavily coated, the bowels torpid. Examination of the abdomen demonstrated the presence of ascitic fluid; the lower extremities were extremely swollen. The woman gave a history of a swelling in the right abdomen, first noticed six years previously; it had enlarged slowly, but had never been at all painful or troublesome. In the spring of 1893 her abdomen began to enlarge, and she was examined by a homeopathic physician, who informed her that she had a "floating tumor," and advised non-interference. Later she had received treatment directed to the general condition from a regular physician of high standing, but the abdominal symptoms progressively became worse.

On tapping, three water-buckets full of clear characteristic ascitic fluid were withdrawn; while not accurately measured, there certainly was not less than thirty-six liters. The patient was immediately relieved, and at once was enabled to assume a reclining posture. Examination of the now lax abdomen revealed a firm movable tumor about the size of an infant's head in the right iliac region, somewhat tender to touch. On being assured that a tumor existed, she announced that she never would submit to operative procedures.

Six weeks later a second tapping was necessary, twenty-four liters being removed, and in January a third tapping withdrew a like quantity. The woman's general condition had improved under treatment, and though the tumor was rapidly enlarging, she persistently refused operation.

Early in March I found her suffering from an attack of epidemic influenza, and in such condition that it was thought that she could not survive the day, much less a fourth tapping, which, other things being favorable, was indicated. I left digitalis and nux vomica, and much to my surprise, a day or so later, learned that she was better, and desired more of the medicine. Her general condition improved to such a marked degree under this treatment that I again urged operation, which she finally accepted, May 14th being the date decided upon. The only available room in the house for operation answered the purpose of best room, general living-room, and bedroom, and was only about 12 x 14 x 7 in its dimensions. It was ordered to be cleaned, and everything was removed except the dining-table, which was utilized as an operation-table. All woodwork was wiped, after thorough cleansing with a sublimate solution, and the patient herself was prepared in the manner usual for abdominal operations.

Assisted only by Hospital-steward Erck, who skilfully administered the chloroform, and Private Hanson, of the Hospital Corps, with a neighbor present who had received a nurse's training in a Chicago school, I operated. A small median incision was made, allowing sixteen liters of ascitic fluid to escape; the tumor proving solid, the incision was enlarged to eleven inches before it could be extruded. There were no adhesions, and the pedicle was not more than three-fourths of an inch in thickness. On casting the silk for its ligation, I found that all the silk prepared for the operation was worthless; it had been boiled for an hour and kept in alcohol until used. Fortunately catgut was on hand, and with this the pedicle was secured and the tumor removed. Digital exploration showed the remaining pelvic organs in normal condition. The peritoneal incision was united by a continuous catgut-suture, the parietes by interrupted catgut, reinforced by a continuous skin-suture; a glass drainage-tube was passed into the pouch of Douglas and secured at the pubic end of the incision, a suture being passed through the edges of the incision here, but not tied. Iodoform, sterilized gauze, absorbent cotton, and gutta-percha tissue comprised the dressing; the tube protruded through the tissue and had a separate dressing, to permit its inspection without disturbing the whole dressing. The duration of operation, from the beginning of the anesthesia, was one hour and fifteen minutes. So skilfully was the chloroform administered that 11 c.c. sufficed.

Evidences of shock were successfully combatted by hypodermics of whiskey and strychnin. The patient was put to bed surrounded by hot bottles, in good condition. She passed a restless night, having persistent nausea, which in a measure yielded to frequent sips of hot water, nothing else being given. On the evening of the operation the temperature was 100.2°, and during convalescence it never rose above 100.8°. Frequent hypodermics of strychnin were given during the night and following day. So great was the discharge of serum that the whole dressing had to be changed on the following morning, and the urine was withdrawn by catheter.

Owing to the distance, the patient was not seen again until Thursday, when the drainage-tube was found to be protruding nearly its whole length from the incision. The nurse said that the woman was passing her urine all right, but the catheter demonstrated a distended bladder, the urine dribbling away—incontinence of retention. The distention of the bladder had forced out the tube; as the discharge seemed to have nearly ceased it was not replaced. The provisional catgut suture to unite the edges about the tube was then taken up, but on inspection it was found that the portion within the tissues had already been absorbed. For several days the catheter was necessary; later a mild cystitis developed, which proved troublesome.

The abdominal incision fortunately united throughout by first intention; the catgut used for the interrupted sutures was defective, and stitch-abscesses developed along the whole incision, discharging for ten days great quantities of pus. Had the interrupted stitch been used through all the tissues, the peritoneum included, the pus would have undoubtedly infected the peritoneal cavity, with fatal results.

It was my intention to use the silk for all tissues, but, as noted, it was worthless at the operation, and the catgut was the only material available. These abscesses and the cystitis retarded recovery, which is at this writing complete. The site of the incision has shrunk to a firm cicatrix, undoubtedly stronger for the suppuration caused by the sutures, and about four inches in length. There has been no return of dropsical conditions, no evidence of a return of the growth, and the patient's general condition is excellent.

The removed tumor was smooth, of a firm fibroid texture, containing no cysts, cutting with resistance, and of a glistening white appearance. It was 5 inches thick, 24 and 21 inches, respectively, in its greater and less circumferences, and weighed 8 pounds; the weight of the fluid removed at the operation was 32 pounds, the total weight 40 pounds.

The following report has been kindly furnished me by Professor Penrose, of the University of Pennsylvania:

"Your report of case and specimen received a few days ago. Microscopic sections show it to be a small spindle-celled sarcoma, *i. e.*, it was composed of a very large number of small spindle cells and many small round cells. Since there were no adhesions, and the pedicle was so very small, the prognosis it seems should be good, yet because of the associated large amount of ascites, and the fact that sarcoma of the ovary usually returns, no definite prognosis can be given. Fibroma of the ovary is almost always small in size, and the shape of the ovary is not destroyed. Fibroid tumors of large size having the same characteristics as were present in your case originate in the uterus. Sarcoma of the ovary is very rare, occurring in the relation of 1 to 100 (?) ovarian cysts. I hope this report is satisfactory, and hope that we may hear from you again.

"Very sincerely,
"Charles B. Penrose,
"Prof. Gynecology Univ. of Pa.
"Per Beyea."

When this patient was first seen the symptoms seemed to indicate hepatic trouble. It was learned later that this was the diagnosis given by the regular physician who had seen her. It was impossible to obtain a consultation with other medical men, but after careful study of the case I was positive in the belief that the tumor was the cause of the dropsical condition. It also seemed probable, in view of its slow development, that it was non-malignant, an ovarian fibroma, though the microscpic examination has shown it to be sarcoma. The operation was performed under difficulties, the unfavorable surroundings, the absence of skilled assistance, and the distance from the post, all rendering it an undertaking the outcome of which could not be assured.

The patient herself, though sixty-six years of age, possessed an amount of courage but seldom seen, and never wavered once in her confidence and belief in the ultimate success of the operation.

Sufficient time has not elapsed to know whether there will be recurrence, but most authorities are inclined to favorable prognosis in such cases.

NOTE.—On November 15, 1894, six months after the operation, the patient was in perfect health, doing her own housework, and maintaining that she had not felt so well for twelve years.

POST HOSPITAL, FORT SULLY, S. D.

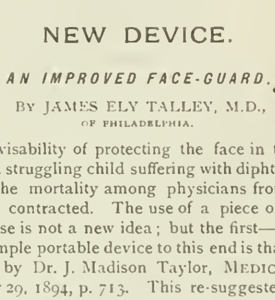
NEW DEVICE.

AN IMPROVED FACE-GUARD.

BY JAMES ELY TALLEY, M.D.,
OF PHILADELPHIA.

THE advisability of protecting the face in the examination of a struggling child suffering with diphtheria finds proof in the mortality among physicians from the disease thus contracted. The use of a piece of glass for this purpose is not a new idea; but the first—so far as I know—simple portable device to this end is that recently described by Dr. J. Madison Taylor, MEDICAL NEWS, December 29, 1894, p. 713. This re-suggested an idea that occurred to me while Resident Physician at the Children's Hospital, but which was not followed up because in the other hospitals in which I served I saw little diphtheria.

The device shown in the cut differs from that already exhibited only in that it can be attached to the band of an ordinary head-mirror.



The points of advantage are that it leaves both hands free, does away with the necessity for a second person to hold it, and moves with the head, and is always in the position desired.

In construction, as little metal as possible should be used, so that the instrument shall not be too heavy. The glass is held in place by a screw running the whole width of the guard, so that it can be easily removed, and readily renewed if broken.

If it be desired to hold it in the hand, it may be used as it stands, or the ball-bearing may be tapped for a screw-handle, after the manner of some laryngoscopic mirrors. Sheathed in a flexible case it may be carried in the pocket or in a bag.

FIFTY-FIFTH STREET AND LANCASTER AVENUE.

MEDICAL PROGRESS.

A Case of Rapid Gliosis of the Spinal Cord.—At a recent meeting of the New York Neurological Society, HOLT and HERTER reported the case of a male child, aged one year, with a good family history, in whom, three months before coming under observation, a weakness was noticed in the right arm and hand, and the head began to droop forward. The motor paralysis in the right arm gradually increased, and finally there was complete loss of power in both arms and in the shoulder-muscles, with atrophy. The muscles of the neck were exceedingly rigid, and the head was carried stiffly, slightly in advance of the normal position, with the face looking directly forward. There seemed to be some loss of power in the legs. The knee jerks were exaggerated, especially on the right side. Ankle-clonus was present on both sides. There was considerable dyspnea, and coarse râles could be heard over the entire chest, but there were no signs of consolidation. The temperature showed irregular daily variations, ranging from 100° to 105°, and even higher. There was occasional vomiting. The pupils were equal, normal in size and responsive to light. There was partial analgesia of the body below the arms. The respirations ranged from 32 to 52 per minute. After the lapse of a month slight strabismus was noticed, and the head was rolled continually from side to side. At times there was marked cyanosis. The temperature rose to 106°, and death took place.

Upon post-mortem examination a grayish, projecting mass was found occupying almost the entire right side of the medulla and a larger part of the left side. The medulla was considerably enlarged from before backward, and from side to side. There was also considerable enlargement of the cord as far down as the eighth cervical segment, and from this point to the sixth dorsal there was some enlargement; below this the cord appeared to be normal. Histologic examination, made at different sections of the cord, revealed a typical gliomatous structure, which involved to a greater or less extent the medulla and almost the entire cord. The appearance of the preparations examined renders it probable that the new formation of glia-cells was derived from the proliferation of the ependymal and peri-ependymal cells. Although the new growth involved almost the entire extent of the cord, it is only to the well-developed growth in the upper half of the cord that the symptoms presented by the patient are to be attributed. The high temperature could hardly be accounted for by the pulmonary condition present, and was probably due to the rapid destruction of nerve- elements in the spinal cord.

Nephrectomy for Sarcoma of the Kidney in a Child Twenty-five Months Old.—At a recent meeting of the Allegheny County Medical Society, at Pittsburg, DR. X. O. WERDER reported the case of a girl, twenty-five months old, that came under observation on account of a small umbilical hernia which had been present for three months. Examination, however, disclosed also a growth in the left hypochondriac region, somewhat larger than an egg. The tumor grew rapidly in size until it occupied the greater part of the left half of the abdominal cavity, extending from the ribs to the crest of the ilium and downward into the left iliac fossa, to within about an inch of the umbilicus, and filling out the left lumbar region. The tumor was not sensitive to touch, and was slightly movable in an antero-posterior direction. The child was plump and healthy in appearance, although there had been some wasting. A diagnosis of malignant disease of the left kidney was made, and nephrectomy advised. Accordingly, an incision about six inches long was made in the left semilunar line, and subsequently enlarged an additional two inches. The peritoneum over the tumor was incised, the very thin surrounding fatty capsule opened and peeled off, and the tumor lifted from its bed, together with the kidney, which was behind and continuous with the growth. The pedicle was ligated at the hilum of the kidney, and included all of its structures; several bleeding points were ligated; the cavity was carefully sponged out and closed without sutures, and the abdominal wound united with silkworm-gut sutures, without drainage. The child stood the operation well. Little blood had been lost. Urination took place spontaneously about two hours afterward, and during the night about ten ounces were passed. The child was dismissed from observation fifteen days after the operation, and subsequently gained considerable flesh. The growth proved to be a rhabdomyo-sarcoma originating from the kidney.

Unusual Malformations of the Brain.—At a recent meeting of the Association of American Anatomists in New York, PROF. BURT G. WILDER showed three remarkable specimens from the collection of Cornell University:

1. An adult human brain with a complete interruption of the central fissure. The total number of such cases recorded does not exceed twenty.

2. A sheep's brain, lacking the callosum or great cerebral commissure. Several human brains with this defect have been described, but the only other cases in animals are three cats, all in the Cornell Museum.

3. A three-months' human fetus with the left olfactory bulb, commonly rudimentary, half as long as the cerebrum, as in most of the lower animals, and containing a considerable cavity. It has long been a belief of Prof. Wilder that the olfactory apparatus is primary and of great morphologic importance; that the recognition of food by smell was once more essential than reflection upon its qualities. The specimen in question, believed to be unique, suggests the possibility of reversion toward a far-off ancestral type.

To Examine the Larynx and to Remove Laryngeal Growths in Young, Nervous, or Unmanageable Children, SPICER (*British Medical Journal*, Nos. 1769, 1770) recommends the preliminary cautious use of a 10 per cent. solution of cocain, followed by the inhalation of chloroform to maintain moderate general anesthesia. An assistant holds the child in the usual position for laryngoscopy, while another stands behind the patient and keeps the head erect and square to the operator; a third assistant stands behind and to the right, holding the mouth-gag; while a fourth holds the tongue out with forceps. In the removal of neoplasms sittings may be repeated at intervals of one or two weeks.

THERAPEUTIC NOTES.

The Treatment of Diphtheria with the Antitoxin.—At a recent meeting of the Clinical Society of London, WASHBOURNE, GOODALL, and CARD (*British Medical Journal*, No. 1773, p. 1417) reported the results of observations made at the Eastern Hospital in 80 cases of children under fifteen, submitted for treatment with the antitoxin of diphtheria. Bacteriologic examination was made in all, but diphtheria-bacilli were found in but 61. Eight of the cases in which diphtheria-bacilli were not found would have been considered not to have been diphtheric had a bacteriologic examination not been made; these were excluded from the statistics. The other 11 at first presented the appearances of diphtheria, but their further progress fully bore out the bacteriologic evidence. Among the 72 cases there were 14 deaths (19.4 per cent.). The significance of this mortality becomes apparent when compared with that of previous years. During the year 1893 there came under observation 397 cases, with 166 deaths (41.8 per cent.); from January 1, 1894, to October 22, 1894, 400 cases, with 144 deaths (36 per cent.); from January 1, 1893, to October 22, 1894, 797 cases, with 310 deaths (38.8 per cent.); from September 14 to October 22, 1894, there were 72 cases not treated with serum, with 28 deaths (38.8 per cent.); from October 23 to November 27, 1894, 72 cases treated with serum, with 14 deaths (19.4 per cent.). Of the 61 cases shown bacteriologically to be diphtheric, 13 died (21.3 per cent.). Among the whole number tracheotomy was required in 9 cases, with 3 deaths. The serum used was obtained from the British Institute of Preventive Medicine and was administered as follows: In severe cases, 20 c.cm. were injected when the patient was first seen, followed by 10 c.cm. in from eighteen to twenty-four hours, and again another 5 or 10 c.cm. in from another eighteen to twenty-four hours. In moderately severe cases a first dose of 10 c.cm. was injected and followed by one of 5 c.cm. the next day, and perhaps another of 5 c.cm. a day later. In mild or doubtful cases, a single dose of 5 c.cm. was injected if there were reason to suspect that the condition was likely to become worse.

HERRINGHAM (*Ibidem*, p. 1428) related that 22 cases had been treated at St. Bartholomew's Hospital with the antitoxin, and that in 4 diphtheria-bacilli were not found. Of the remaining 18, 7 were mild and all recovered; 5 were severe; 6 very severe. Tracheotomy was required in 10 of these 11, with 3 deaths, and in 1 intubation. In previous years tracheotomy had been performed in 63 cases, with 41 deaths.

KOSSEL (*Deutsche medicinische Wochenschrift*, 1894, No. 51, p. 946) has made a further report upon the use of the antitoxin in the treatment of diphtheria at the Institute for Infectious Diseases in Berlin. From March 15 to December 1, 1894, there came under observation 119 cases, of which 2 were moribund and were not treated with the antitoxin. Among the 117 there were 13 deaths (11.1 per cent.). There came under observation on the first day 14 cases, all of which recovered; on the second day 30 cases, with 29 recoveries; on the third day 29 cases, all of which recovered; on the fourth day 9 cases, with 8 recoveries; on the fifth day 11 cases, with 9 recoveries; on the sixth day 6 cases, with 3 recoveries; on the seventh day 5 cases, with 3 recoveries; on the eighth day 6 cases, with 3 recoveries; on the ninth day 1 case that died; and on uncertain days 6 cases, with 5 recoveries. Bacteriologic examination was made in all cases; in 2 diphtheria-bacilli could not be found, but in 1 of these a complicating otitis media developed, and was attended with perforation, and in the pus discharged diphtheria-bacilli were present.

The mortality in the children's department of the Charitié, among cases not treated with antitoxin, was, in 1889–90, 52.4 per cent.; in 1890–91, 60.1 per cent.; in 1891–92, 62.8 per cent.; in 1892–93, 56.4 per cent. In 23 of the cases treated with the antitoxin, tracheotomy became necessary, with 11 recoveries (47.8 per cent.). Of the 104 cases in which recovery ensued, 57 were free from albuminuria, which was present in 41. Of the latter the albuminuria persisted but a single day in 9 cases; for two or three days in 11; for from four to seven days in 9; and for longer periods in 12. In 10 of the 13 fatal cases albuminuria was present on admission. Paralyses developed in 19 of the 104 cases that recovered. In 5 cases the action of the heart was disturbed. No relapse was observed. As to dosage, recent cases received 600 immunity-units; cases with doubtful prognosis, 1000 immunity-units; and cases of long duration, 1500 immunity-units.

TREYMANN (*Ibidem*, p. 951) has reported the case of a child, three years old, in which acute hemorrhagic nephritis developed in the sequence of an attack of diphtheria of moderate severity treated with the antitoxin. The child came under observation on the third day of the disease, and at once received an injection of serum No. 2 (1000 immunity-units), and on the following day an injection of one-half the dose of serum No. 3 (750 immunity-units), which was repeated a day later. For a time improvement manifested itself, but in the course of two weeks the membrane in the throat reappeared, and a further injection of serum No. 1 (600 immunity-units) was given. On the following day albumin appeared in the urine for the first time; the renal secretion became scanty in amount and hemorrhagic in character, and microscopic examination disclosed the presence of red and white blood-corpuscles, with tube-casts and epithelial cells. Several days later complete anuria developed for twenty-four hours, with edema of the eyelids, but the condition gradually subsided and progressed to ultimate recovery.

In contrast with the preceding case SCHWALBE (*Ibidem*, p. 952) has reported the case of a child, ten-and-a-half years old, in which acute hemorrhagic nephritis developed in the course of an attack of diphtheria not treated with antitoxin.

REMBOLD (*Ibidem*, p. 963) has reported the case of a girl, seven-and-a-half years old, in which paralysis of accommodation developed in the sequence of an attack of diphtheria treated with the antitoxin. Two injections each of serum No. 1 (600 immunity-units) were made on the second and third days of observation respectively. The visual defect was noted several weeks after recovery from the primary disease. In a second case in a girl, eleven years old, a single injection of serum No. 1, made on the first day of observation, was followed in nine days by the appearance of a scarlatiniform exanthem upon the upper and lower extremities. Two days later the child complained for a few hours of pain in the sacral region and in the lower extremities, and for five days there was inability to stand. The eruption gradually disappeared in the course of four or five days, and recovery was ultimately perfect.

A Pemphigoid Eruption Following the Administration of Copaiba.—SEQUEIRA (*British Medical Journal*, No. 1768, p. 1108) has reported the case of a man, twenty-eight years old, who, for the relief of a slight attack of urethritis, took three capsules of copaiba at night, followed by five on the following day. After the lapse of another day the face became swollen and red, and the body covered with red patches. In the evening several blisters appeared on the legs. When seen, the face was slightly swollen and red, and the arms and thighs presented irregular erythematous patches somewhat raised above the surface. Upon the lower portion of each leg over the tendo Achillis were large bullæ about the size of a small hen's egg, together with several smaller ones, six on the right and five on the left. The walls of the bullæ were strong and tense and contained clear serum. They were not surrounded by areolæ, and after rupture the exposed skin rapidly closed over under treatment.

In the Treatment of Pleural Effusion SÉGALÉA (*La Médecine Moderne*, 1894, No. 101, p. 1580) has employed with success topical applications of guaiacol in the following formula:

℞.—Guaiacol . . . . . ♏ xxxvi.
Glycerin
Tincture of iodin } . . āā f℥ss. M.

The applications are made by means of a brush to the entire posterior aspect of the chest, which is then covered with cotton and an impermeable dressing and a bandage.

In a case of anasarca, with anuria, in the sequence of scarlatina, in which other measures had failed, applications of the following combinations were soon followed by relief:

℞.—Guaiacol . . . . . ♏ xvi.
Glycerin . . . . . f℥ss. M.

In the Treatment of Trachoma, GRAY (*Journal of the Arkansas Medical Society*, vol. v, No. 2, p. 55) recommends the employment of a powder of resorcin (one part) and boric acid (five parts). The eyelid is strongly everted and thickly dusted by means of a camel's-hair brush with the powder, which is well rubbed in with the end of the little finger. In order to reach granulations in the retro-tarsal fold, the flat, blunt end of a nail-cleaner of bone or ivory is used. The pain resulting from the application lasts for from a few minutes to nearly an hour. The frequency of application is governed by the effect, as shown by the degree and duration of the irritation. In some cases an acute granular conjunctivitis may be induced. The treatment is applicable to advanced cases of chronic diffuse trachoma, but not to cases of acute or follicular trachoma.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

SATURDAY, JANUARY 12, 1895.

THE NATURE, ACTION, AND SPECIFICITY OF ALEXINS AND ANTITOXINS.

THE conditions underlying natural or inborn immunity are quite different from those concerned in acquired immunity. Many different theories have been advanced to explain the nature of the former, but no one of them is altogether satisfactory. According to some authors, headed by BAUMGARTEN and PETRUSCHKY, natural immunity is often due to the absence in the animal of nutriment of a character suitable for assimilation by the specific bacterium that causes the disease. Although this hypothesis may have a basis of fact in a certain number of instances, it will by no means explain all cases of natural immunity.

It is quite possible that in some animals a natural immunity to many microörganisms is directly dependent upon certain physiologic peculiarities. Thus KARLINSKY states that the immunity from anthrax which snails possess is partially due to the acid that they manufacture, and a similar explanation may hold good for the local immunity (*e. g.*, from anthrax) seen in many animals when the virus enters the stomach.

Undoubtedly, in attempting an explanation of this question many factors have to be considered, and on close examination the safeguards with which the higher animals are provided will be found to be manifold and often complex. When we remember that we constantly carry about with us in the cavities, as well as on the surface, of our bodies, microörganisms that under favorable conditions are capable of giving rise to serious and sometimes fatal infectious processes, the importance of a due appreciation of the natural resisting powers of the body becomes easily evident. While the integrity and well-working of the local defensive mechanisms (*e. g.*, epithelial membranes, ciliated surfaces, antiseptic secretions), which in the main are either mechanic or chemic in their action, are of the highest importance in determining susceptibility, we know that even when pathogenic bacteria have eluded these peripheral sentries the body still holds in reserve active agencies for combatting their growth and multiplication, and is often still capable of destroying them completely. According as these mechanisms are efficient or inefficient in protecting against a specific bacterial virus, we can speak of an individual as being insusceptible or susceptible to infection with that bacterium and to the particular disease to which it gives rise.

The efficacy of the machinery of defence varies with the general nutrition, so that an animal may at times prove susceptible to a virus from which the species is ordinarily immune. Further, the differences in susceptibility which various species show to infection with the same variety of bacteria have long been known, and can only be explained by the assumption of corresponding variations in the defensive mechanisms.

The nature of the internal protective processes, with the exception of the filtration by organs such as the lymph-glands and the spleen, has been much disputed. One class of investigators attribute the main credit of the internal natural resistance to an active warfare waged by certain cells of the body, of mesodermal origin, especially the leukocytes and endothelial cells; the members of another school claim that it is in the germicidal power of the fluids of the body that the explanation of natural immunity must be sought, and that the phenomena usually classed as chemotaxis and phagocytosis are secondary and subordinate.

That the blood-serum when removed from the body does possess definite germicidal power has been proved beyond a doubt, notwithstanding the objection of VON CHRISTMAS, who stated that it was only the old and degenerate bacteria which, when introduced, did not multiply, and that of JETTER, METSCHNIKOFF, and HAFFKINE, who believed that the results that had been adduced in support of the idea of a germicidal activity of the serum were not specific, but were rather to be looked upon simply as due to the injurious effects that are known to follow the sudden transference of bacteria from one medium to another of different concentration.

That extra-vascular blood-serum exercises a germicidal influence does not, of course, prove that the blood within the vessels of the living body possesses the same power. It has even been urged that the appearance of germicidal activity in the serum may follow and depend upon degenerative changes in the blood that only come about after its withdrawal from the body.

It would take too long to enter fully here into the arguments dealing with the question. It may be stated, however, that direct experiments have been made by BUCHNER, STERN, and ENDERLEN to show that the intra-vascular blood possesses definite germicidal power.

Again, it is claimed that the germicidal activity of blood-serum is most marked immediately after its removal from the body, and, further, that the blood of animals naturally immune from anthrax is more actively bactericidal than that of susceptible animals, although there are several experiments, the results of which appear to contradict this latter statement. The facts that the toxins of bacteria can completely destroy the germicidal power of serum (LUBARSCH), and that rattlesnake-poison completely abolishes it (WELCH and EWING), are in favor of the view that the germicidal activity is normally possessed by the intra-vascular blood.

The germ-killing power of the blood-serum has been shown to depend upon the presence in the latter of certain chemic substances very complex in their nature, presumably allied to the albumins, and which have been called by BUCHNER, alexins, and by HANKIN, defensive proteids. It is probable that the alexins have their origin in the cells of the tissues. These substances, whatever they are, are very unstable bodies that soon disintegrate after leaving the animal body. Heating to the temperature of from 50° to 55° C. for half an hour destroys them, as does the prolonged action of light or an excessive supply of oxygen. As we have had occasion to point out before in these columns, when writing of the teleology of sunburn and tan, it would seem as if it were by no accident that the blood and organs are buried within the body as in a dark chamber.

The alexins are even more unstable than the enzymes, such as trypsin and papayotin; but, unlike the unformed ferments, they are incapable of causing hydrolytic cleavages, though they can destroy bacteria against which the ordinary ferments are inactive.

It would appear that the same substances on which its germicidal activity depends are also responsible for the well-known globulicidal power of the blood-serum; that is, the power of destroying the red and white blood-corpuscles of an animal of a different species.

One curious fact that has been made out is that the activity of dogs' serum or of rabbits' serum is diminished by the addition of water, but can be reestablished by adding an amount of sodium chlorid sufficient to restore the normal concentration of the fluid. The action of salt appears to be only indirect, its presence rendering possible the action of the serum-alexins, and potassium and ammonium chlorids, as well as potassium, sodium and ammonium sulphates, exercise the same influence as the sodium chlorid. The addition of sulphates of the alkalies to the diluted serum increases the activity of the alexins and heightens the resistance of the latter to the effects of heat so that they can withstand a temperature higher by at least 10° C. BUCHNER maintains that the addition of the salt to the serum increases its resistance to heat by extracting water from the alexins, and, in order to account for the complexity of the bodies, suggests that they may not be simply substances in molecular solution, but that the serum may represent a micellar solution, an explanation which it may be remembered was long ago suggested by NÄGELI for the differences between crystalloids and colloids.[1]

---

[1] Buchner even suggests the possibility of the existence of chains or bands of micellæ with water-molecules lying between the individual members of the chain. If the entrance of salt into the interior of the micellar bodies or chains was prevented, then, according to the laws of osmosis, the surrounding fluid, as it increases in concentration, must remove water from the micellæ or micellar bands. Again, a diminution of the amount of salt in the surrounding fluid would lead to an increase of the water in the micellæ. The latter change would lead to swelling, the former to increased consistence of the micellar structure, and hence to increased resistance to an external agent such as heat. Buchner lays considerable stress on the distinction between active and inactive albumins, and thinks that the differences may possibly be explained by alterations in the micellar arrangement of molecules that are chemically constant.

As much or more difference of opinion exists concerning the nature of acquired immunity as concerning the natural resistance that an organism offers to infection. While there is evidence that through artificial means the natural resistance can be increased, yet it would seem that in acquired immunity the protection does not depend upon the same factors as are concerned in natural or inborn immunity. In acquired immunity the blood-serum of the animal possesses definite antitoxic power against the toxins of the bacterium against which it has been immunized when injected with them into a susceptible animal.

The substances in the blood-serum of immunized animals upon which the antidotal power is dependent are very different from the alexins of normal blood-serum. The antitoxins are tolerably stable; moreover, so far as is known, unlike the alexins, they are not variable according to the species of animals from which they come, but are dependent upon a reaction to the toxins of the variety of bacteria from which the animal is rendered immune.

If the blood-serum of an animal naturally immune from a certain bacterial infection be introduced into the body of an animal naturally susceptible to the same infection, so far as is known little or no protection is afforded by the procedure. In acquired immunity and in cases in which an animal has been rendered "poison-proof," the antitoxins are transferable to another animal, and a temporary and *passive* immunity is conferred upon the latter. This transferred immunity must not be thought, however, to be paramount to the immunity gained by an animal by the injection of virus or toxins. In the latter case the body of the animal has suffered a reaction to the toxins; the immunity is *active*, and the cells of the body go on producing antitoxic substances even after large quantities of blood have been removed from the animal. In the animal that has only *passive* immunity, on the other hand, it is believed that the cells do not manufacture the immunifying substances, so that the period of immunity will depend mainly upon the amount of antitoxic serum introduced, and the protection will gradually become less sure as the antitoxic compounds are gradually eliminated from the blood through the excretory organs.

We have in a previous article pointed out that the term antitoxin is badly chosen, since its use might create an impression that a direct destruction of the toxins is understood to occur. Buchner succeeded in preparing antitoxic substances in a dry condition from the blood-serum of animals rendered insusceptible to tetanus, and mixed them with dry tetanus-poison. On injection of this mixture into white mice the animals were not disturbed, though when introduced into guinea-pigs in the same proportions it gave rise to distinct symptoms of tetanus. Buchner believes that this experiment alone is proof that the tetanus-poison and the antitoxin act separately in the organism, the latter rendering the tissues and cell-territories less susceptible to the action of the former. Since the cells of the guinea-pig require more antitoxin to render them insusceptible to the toxin of tetanus than do those of the white mouse, the specific organization of the body of the animal in which the mixture of poison and antidote is being tried must be looked upon as representing an essential factor in the result.

Buchner views the antitoxic activity as an immunizing influence that acts rapidly; but, however this may be, it seems certain that the antitoxins of themselves are not capable of multiplying within the body, and that alone they are incapable of bestowing the peculiar imprint upon the cell-metabolism that, in the immunity acquired through the action of bacteria or their toxins, leads to the manufacture of antitoxic substances.

Roux and Vaillard proved that with mixtures of toxin and antitoxin, even when the antitoxin predominated, the phenomena of tetanus could be set up if an animal were previously weakened in any way, or if the products of other bacteria were injected at the same time. It would thus appear as though the tissues and cells of a weakened organism were not able to utilize the antitoxins so as to make themselves insusceptible to the poison in the same degree as those of a healthy organism. A very interesting observation in this connection is recorded by Calmette, Phisalix, and Bertrand, who showed that the serum of animals rendered immune from snake-poison possesses antitoxic power. When the antitoxin was added to snake-poison in sufficient quantity to render the mixture on injection inactive it was found that on heating the same mixture to 70° C. (a temperature that destroys the antitoxin) the poison again became active.

Finally, observations concerning the specificity of the healing substances have to be mentioned. It has always been believed that the antitoxic substances in the serum of an immunized animal were of a specific nature, that is to say, that the serum of an animal immunized against diphtheria, for example, would be powerless against the toxins of bacteria other than diphtheria-bacilli, or, in other words, that the substances antitoxic to the products of a specific bacterium could be made inside the body of a living animal only through the action of the same bacterium or its products. The confidence in this doctrine of the specificity of the antitoxins contained in the serum of immunized animals is already shaken.

In the first place, bacteriologists are coming more and more to the view that the products of all bacterial metabolism have much in common, that is to say, that bacteria of different kinds may produce similar or identical poisons, although in very different amounts. The investigations of Centanni on the cause of the fever in the infectious diseases tend to show that almost all bacterial forms produce a common pyrogenic substance, the so-called *pyrotoxina bacterica*.

Roux states that while the normal blood-serum of the horse exercises no effect on cobra-poison, the blood-serum of a horse immunized from tetanus when mixed with cobra-poison renders the latter harmless on injection, and this notwithstanding the fact that the physiologic effects of the toxins of the tetanus-bacillus and of cobra-poison are by no means analogous. The serum of an animal rendered immune from snake-poison does not, however, possess any protective influence against the toxins of tetanus. The serum of an animal immune from tetanus is more actively antitoxic to tetanus-poison than to snake-poison, but the difference appears to be a quantitative, not a qualitative one.

Again, the normal blood-serum of a rabbit has no antitoxic influence on snake-poison, but the blood-serum of a rabbit immunized against hydrophobia is also protective against snake-poison, and will often prevent the injurious effects of from four to five times the ordinarily fatal dose. It is claimed, further, that the serum of animals immunized from snake-poison makes rabbits more resistant to the toxic effects of abrin, and that antiabrin increases the resistance of a rabbit to the action of snake-poison.

The whole subject grows more interesting as it increases in complexity. At the present time sweeping statements are not allowable, for, as Lubarsch has said, "what is written on immunity to-day may, when it appears in print to-morrow, be already old."

EDITORIAL COMMENTS.

Laminectomy for the Relief of Spinal Compression.—It can scarcely be said that the results of surgical intervention for the relief of compression of the spinal cord resulting from fracture, caries, hemorrhage, neoplasm or what not, have been altogether encouraging; but in a condition in which non-interference must in many, if not most, instances prove inevitably fatal the unfortunate victim should at least be given the chance afforded him. In cases of a chronic and non-progressive character good may be hoped for from expectant and conservative treatment, but in cases of acute compression, or in which the lesion and symptoms are progressive, and in cases in which the diagnosis is in doubt, laminectomy would be justified. Recent medical literature has contained reports of numerous cases in which this operation has not been attended with the expected results. It is, therefore, a satisfaction to be able to cite an instance[1] in which the outcome was favorable. The case was under the observation of Mr. Noble Smith, of London, and occurred in a woman, thirty-one years old, whose spine had been injured by lifting a heavy weight four years before coming under observation. The accident was followed by pain and weakness, not only in the back, but also in the lower extremities. A felt jacket was applied, but with little relief. The symptoms gradually progressed until walking was interfered with. A distinct angular projection was present, its most prominent point corresponding with the tenth dorsal vertebra. Efficient mechanical support relieved the pain in the back, and the patient improved both as regards the general health and the weakness in the back. The vertebræ seemed to become consolidated. A feeling of coldness in the lower extremities and great difficulty in walking, however, remained.

A course of rest, with massage and special feeding, was followed by relief for a short period, but subsequently the difficulty of walking became more pronounced. For a year the patient had been obliged to use crutches. For several years there had been pain of a neuralgic character in the region of the sacrum, gradually increasing in acuteness, with periodic attacks of greater severity. The pain was less when the patient was quiet, but was induced by attempts at walking. The patient was able, when standing between two chairs and supporting herself on them, to lift the knee of each leg up about four inches, and backward to about the same extent. The knee-jerk was natural, and there was no ankle-clonus. There was dulness of sensation upon the anterior and posterior aspects of the thighs and in the legs, and hyperesthesia upon the buttocks and over the sacrum. Laminectomy was decided upon, and the neural arches of the eighth and ninth dorsal vertebræ were removed. There was no fat over the dura mater, which was congested, and in the upper part of the opening in the position beneath the removed arch of the eighth vertebra was found a spongy material like granulation-tissue. This appeared to be the source of pressure upon the cord, and was removed. It covered the dura mater as far downward as it was exposed transversely, being rather thicker on the right than on the left side.

---

[1] British Medical Journal, No. 1770, p. 1232.

The amount removed was about equal to the contents of an ordinary hazelnut. The patient made a rapid recovery from the operation. The wound appeared quite healed from the third day after the operation, except at the lower part, where a drainage-tube had been left for twenty-four hours. The day following the operation the patient remarked upon the great difference in her sensations, having lost the cold feeling from which she had suffered for several years. She gradually recovered strength, and with a supporting apparatus began to walk about three weeks after the operation. Five months after the operation the former coldness in the lower extremities had not returned, the digestion had improved, and headache and spasmodic jerking of the limbs, which had been present, were gone.

Prenatal Endocarditis.—Our views upon the etiology of endocarditis have hitherto been altogether too narrow. We have been satisfied to believe that in most cases the endocardial inflammation was to be ascribed to an attack of rheumatism, obvious or overlooked, and have ignored the multitude of other factors that may act in a causative way. Rheumatism causes endocarditis either by infection or by intoxication. Any other condition capable of acting in the same way may also give rise to endocarditis —or, as a matter of fact, to inflammation of any or several of the serous membranes. The well-known clinical fact that the left side of the heart is almost invariably alone attacked by endocarditis is explained by the great functional activity of this side. Reasoning on the same line, one would look for right-sided involvement when the endocardial inflammation occurred during intrauterine life. Another explanation for this localization is the transmission of the infection through the placental circulation.

ZARIQUIEY (*Maladies de l'Enfance*, November, 1894, p. 620) has reported a case of right-sided endocarditis that could be used in support of this assumption. It occurred in an infant that at birth presented marked cyanosis, especially upon crying, with a certain degree of dilatation of the veins of the trunk and head and hyperemia of the conjunctivæ. Upon auscultation the normal heart-sounds were heard at all of the orifices, as well as a murmur following, but not obscuring, the first sound, and occupying the period of silence. This murmur was soft and prolonged, and audible over the whole cardiac area, but it was heard with greatest intensity at the base upon the left, and was propagated toward the clavicle upon the same side. There was no edema, and the pulse was normal. At the age of nine months the child had an adeno-phlegmon below the left angle of the lower jaw, and at the age of ten months an exfoliative glossitis. In the eleventh month it died of an extensive phlegmonous process of the scalp. Upon post-mortem examination the heart was found to be slightly increased in size as the result of hypertrophy of the right auricle. The coronary veins were tortuous and distended with blood. The tricuspid orifice was narrowed, and the foramen ovale was closed in its posterior two-thirds by a thick fibrous membrane, while the anterior third was divided by a fibrous band passing from the anterior margin of the membrane to the anterior margin of the foramen. The walls of the right ventricle were considerably thickened, while its cavity was reduced in size. The tricuspid ring was thickened, hard, and large. Its leaflets were short and rigid, and the orifice was reduced in size. The pulmonary orifice was so contracted as scarcely to permit the entrance of a probe.

It seems reasonable to conclude that the lesions in this case were due to an inflammation of the endocardium of the right side of the heart during fetal life, and that this was in all probability in its turn due to irritants present in the maternal circulation.

The Treatment of Varicose Ulcers.—One of the most troublesome conditions with which the physician has to deal is that of chronic ulceration of the lower extremities. The affection can be usually traced to a depraved constitutional state, usually in conjunction with circulatory atony, local or general. Many modes of treatment have been recommended, but none is efficacious in all cases. To be successful, therefore, one's resources must be extensive. To the plans already in use SUMMERS (*Medical Record*, No. 1255, p. 655) adds another that commends itself for its simplicity. He has reported the case of a woman, fifty-six years old, who had suffered from chronic ulcers of the legs for many years; the veins, from the knees down, were much dilated and the cutaneous circulation was poor. The treatment consisted in cleansing the ulcers with a solution of sodium bicarbonate, followed by the application of a solution of methyl-violet, care being taken to bring this in contact with the entire area of the base and margins. After allowing the fluid to dry, each stained ulcer was covered with a bit of absorbent cotton, and mechanical support was furnished by an elastic bandage. The entire procedure was repeated every morning. In the course of a few days it was evident that healing had begun, and in the course of several weeks perfect recovery had taken place. We are confident that proper mechanical and gravitational support must play an important part in every form of treatment for varicose ulceration of the lower extremities from which good results are to be expected.

Decrease of Population in Ireland.—From information contained in the annual reports of the registrar-general of Ireland, it appears that the population of Ireland reached its maximum in 1845, when it was estimated to be 8,295,061. A slight decline took place in 1846, but the serious decrease commenced in 1847, the year of the potato famine. During the seven years between 1846 and 1853 the population diminished two million. Since 1853 the decrease has continued at a fluctuating rate. In the middle of 1894 the population of Ireland was estimated as 4,590,700. In the decade from 1841 to 1851 the decrease was 19.9 per cent.; in that from 1851 to 1861, 11.5 per cent.; in that from 1861 to 1871, 6.7 per cent; in that from 1871 to 1881, 4 4 per cent., and in that from 1881 to 1891, 9 1 per cent. In 1891 there were on an average 4.3 acres of land to each enumerated inhabitant, including infants and children, whereas in 1871 and 1881 the proportions were 3.7 and 3.9 acres respectively. These changes are attributed to the serious and repeated failure of the potato crop and to the marked deficiency of manufacturing and industrial occupations for the inhabitants. It is maintained that notwithstanding the falling off in population the aggregate wealth has considerably increased.

Laboratory-Teaching of Large Classes.—At the recent meeting of the American Society of Naturalists, in Baltimore, a communication from PROF. BURT G. WILDER was read, stating briefly the experience at Cornell. The system of Practicums (as distinguished from the laboratory-work of the more special or advanced students) was introduced in 1880 for Vertebrate Zoology, and in 1886 for Physiology. The classes range from 40 to 180. Japanese napkins are used in place of towels. The students seem to enjoy the work. In 1892 a rack was devised, something like a long music-rack, clamped along the middle of a wide table, for holding the text and plates of dissections. Professor Wilder urged that all this work be included in the requirements for admission to college, and cited as a practical argument the inconvenience of storing in alcohol or formalin so many somewhat bulky specimens; for instance, about 170 each of sheeps' hearts and brains, and entire cats.

Cardicentesis, with Recovery.—The ability of vital organs to recover from direct traumatism of a profound character is well illustrated by a case reported by SLOAN (*British Medical Journal*, No. 1772, p. 1368) at a recent meeting of the Edinburgh Medico-Chirurgical Society, in which puncture of the heart with the escape of a considerable quantity of blood was unattended with evil results. The case occurred in a woman, nineteen years old, who, in a fourth attack of acute rheumatism, complicated by endocarditis and pericarditis with effusion, appeared to be *in articulo mortis*, when a trocar was suddenly introduced for the purpose of evacuating the fluid. About ten ounces of blood escaped, apparently from the right ventricle. No bad symptoms followed, but, on the contrary, improvement soon set in, and the case progressed to ultimate recovery.

REVIEWS.

A MANUAL OF MODERN SURGERY, GENERAL AND OPERATIVE. By JOHN CHALMERS DA COSTA, M.D., Demonstrator of Surgery, Jefferson Medical College. Philadelphia: W. B. Saunders, 1894.

THE purpose of this book is "to stand between the complete but cumbrous text-book and the incomplete but concentrated compend." Certainly this is a most laudable object, particularly as teachers of surgery, as of other branches in medical schools, are awakening to a realization of the great value of the recitation in the place of many a lecture in the formal course; are beginning to perceive that an exercise for which the student must prepare himself, and in which he must take a conspicuous part, either to his credit or shame, has educational advantages over the system in which the lecturer only is active, and his hearers merely passive receptacles of his words of wisdom. There is a growing demand for text-books from which the student may learn his recitation. The large work, which comes near supplying the needs of the busy physician, is too extended for the student, and the compends, so compressed that all the flavor, excepting that of a dictionary, is squeezed out of them, fall far short of reasonable requirements. Just what things to insert, and how much they should be condensed, are questions upon which no two teachers, of equally large experience, will agree absolutely; and, therefore, no critic can approve entirely of the selection and treatment of topics in any book. In order to secure perfect accord the author and critic must have been cast in the same mold, and have had identical environments—conditions manifestly impossible.

Dr. Da Costa has, however, in most respects, succeeded so well in his attempt that we predict the adoption of this volume as a class-room text-book by many teachers, and the preference for it by their students over other books that they have used. The author is evidently a good student of surgical literature, and is thoroughly imbued with the most advanced ideas. His style is easy, clear, and direct, and his judgment in selection generally excellent. But, though we can say so much in praise, there are various things upon which we entertain opposite views; and we feel obliged to offer our hearty disapproval of some of his positions. He omits entirely the consideration of diseases of the breast on account of "limited space," while devoting thirty pages to the matter of ligation of arteries in their continuity. The former subject is constantly presented to the general practitioner, is of the gravest importance, and is not usually treated in works on gynecology. The latter comes up for practical consideration but rarely, and is so largely anatomic that a good knowledge of topography is alone almost sufficient equipment for its management. We trust that this serious disproportion will be corrected in the subsequent editions which we expect will be called for.

ATLAS UND GRUNDRISS DER TRAUMATISCHEN FRACTUREN UND LUXATIONEN. Von PROF. DR. H. HELFERICH in Greifswald. Mit 166 Abbildungen nach Originalzeichnungen von DR. JOS. TRUMPP. München: J. F. Lehman, 1895.

THIS excellent little book is one of a series of "Hand-Atlanten" on various branches of medical science which admit of pictorial illustration. It is intended to afford to students an introduction to the important study of fractures and luxations, and to serve as a useful guide to practising surgeons. At first sight it might impress one as belonging to "cram" literature, against which there is a not altogether unwarranted prejudice. But it is really a book to be studied and carefully digested. It is very concisely written, and contains sixty-four lithographic plates and four process-pictures. For some of the plates the drawings were made from the living subject; for some, from museum specimens; and for some, lesions artificially produced upon the cadaver. It is these illustrations which constitute the Atlas. Each plate has a page of descriptive text. The process-pictures are reproductions of photographs from life.

The Grundriss (literally translated, ground-plan) consists of five sections. The first deals with the general subject of both classes of injuries. In the second fractures of the skull are discussed. The third is on the fractures and luxations of the bones of the face and chest; while the fourth and fifth are devoted to these lesions as affecting the upper and lower extremities respectively.

All these topics are set forth in succinct terms, but in a most practical manner. The author, whose name in well known in German professional literature, is obviously a surgeon of wide experience and of truly conservative views. We are quite sure that this product of his pen will be highly appreciated by all those whose familiarity with the language enables them to avail themselves of its teachings. We should be glad to welcome it in an English translation.

HEALTHFUL WOMANHOOD AND CHILDHOOD. By HENRY BIXBY HEMENWAY, A.M., M.D. 8vo., pp. 270, and Index. Evanston, Ill.: V. T. Hemenway & Co.

"IGNORANCE is not purity," says Dr. Hemenway in the introduction to his work, nor is it modesty. The time when the organic functions were shrouded from all but physicians, in a mist of medieval ignorance and superstition, and were popularly regarded with mingled feelings of curiosity and disgust, is well-nigh past. Intelligent men and women to-day are not ashamed to learn the physiology of respiration or digestion, and if the physiology of reproduction is approached with hesitation born of sensibility and diffidence, a sense of the profound importance of the knowledge prevails, and places its propriety beyond question.

In this book the author treats of the physical life of woman from girlhood to the climacteric: of menstruation, pregnancy, parturition, and many related matters, of embryology and the care of the child, and always in a delicate yet straightforward manner, and in untechnical language adapted to the comprehension of the nonprofessional reader. One may take occasional exception to a statement, or question the wisdom of detailing some of the information conveyed, but on the whole the book is simple, wholesome, and scientific. It merits the attention of physicians, and is to be recommended for the perusal of intelligent parents.

LANDMARKS IN GYNECOLOGY. By BYRON ROBINSON, B.S., M.D., Professor of Gynecology in the Chicago Post-Graduate School, etc. The Physician's Leisure Library. Detroit: George S. Davis, 1894.

PROFESSOR ROBINSON considers as the landmarks of chief importance in gynecology the following: Anatomy, menstruation, labor, abortion, gonorrhea, and tumors. The first four of these are treated in the present volume, the lectures being largely based upon personal work in dissections, from which are derived a number of original views and new classifications. Much that is valuable and instructive is set forth in an interesting manner, although some of the views held by the author are not in accord with the generally accepted teachings of the day. Thus, he believes in the supporting function of the uterine ligaments, and regards the gluteus maximus muscle rather than the levator ani as the muscle of copulation; he heartily indorses Tait's perineorrhaphy in preference to Emmet's operation. Nevertheless, the book is cleverly prepared and makes interesting reading.

ESSENTIALS OF DISEASES OF THE SKIN. By HENRY W. STELWAGON, M.D., PH.D., Clinical Professor of Dermatology in the Jefferson Medical College. Small 8vo., pp. 261, and Index. Revised edition. Philadelphia: W. B. Saunders, 1894.

IN the preface to this edition of his well-known compend the author says that in making "corrections and additions" the object has not been to extend the text and comparison with the earlier edition shows that this has been attained. The changes, including the additions, are purely revisory, and are based upon recent clinical observation and histologic investigation, as, for example, those on the pathology of seborrhea, the clinical characteristics of seborrheic eczema, the erysipeloid condition affecting the hands of butchers, having its origin in a wound and depending on infection from putrid flesh. Among the additions noted is a description of pityriasis rubra pilaris.

The illustrations of the former editions have been increased in number by the insertion of several new halftone plates, which, as usual, are only partially satisfactory. It is doubtful if even the best can convey to the uneducated eye an adequate impression of the configuration of the lesions they portray. They will, however, be useful to the student helping to fix in his mind their distribution.

DIRECTIONS FOR LABORATORY WORK IN BACTERIOLOGY. By FREDERICK G. NOVY, M.D., Sc.D., Junior Professor of Hygiene and Physiological Chemistry in the University of Michigan. 8vo., pp. 205, and Index. Ann Arbor, Michigan: George Wahr.

THIS book has been prepared for the use of students of medicine in the University of Michigan, and is designed as a guide to progressive laboratory work in bacteriology. The preliminary exercises are devoted to elementary technique—sterilization of apparatus, preparation of media and culture, staining for microscopic examination—and to the study of the morphology and classification, and the structure and vital manifestations of bacteria. These are followed by schemes for the systematic study of species. In each scheme the morphologic, biologic, cultural, and pathogenic characteristics are indicated, along with the source, historic data, and synonyms. The exercises include the examination of bacteria in water, soil, and air, in sputum and tissues, also methods of inoculation, post-mortem examinations, and the testing of antiseptics. The book is interleaved for the purpose of making sketches and additional notes, and as a supplement to the more elaborate treatise will no doubt be helpful to the student.

THE ELASTIC TISSUES OF THE SKIN: ITS DISAPPEARANCE AND REGENERATION IN RELATION TO PATHOLOGICAL PROCESSES. By DRS. PASSARGE and KROESING. Hamburg and Leipzig: Leopold Voss, 1894.

THIS brochure takes up and discusses the subject in a most thorough manner. A few practical points may be alluded to. The authors find that in all inflammatory and hyperplastic formations (new growths) the elastic tissue disappears in proportion to the intensity of the pathologic process present. It is especially damaged by the infiltration which occurs. It disappears in general only when infiltration has existed. The beginning of degeneration is shown through loss of staining power and a thickening of the caliber of the fiber, which ultimately ends in molecular destruction. Regeneration of the fibers, as concerns the lighter grades of the infiltrating processes, does not seem to take place.

TRANSACTIONS OF THE STATE MEDICAL SOCIETY OF WISCONSIN FOR THE YEAR 1894; vol. xxviii.

THE usual assortment of material is to be found in this volume of *Transactions*, which differs little from other publications of a like nature. Probably the most attractive features are the papers treating of the tonsils and their pathologic states, participated in by Drs. Farnham, Neilson, Rogers, von Szoldrski, and Waterman, and those upon conjunctivitis by Drs. Würdemann, Zimmermann, Bach, and Neymann. Dr. B. Robinson, of Chicago, contributes a paper entitled "Observations on Eighty Recently Performed Laparotomies."

NEWS ITEMS.

Munificent Gifts to Columbia University.—Within the last six weeks Columbia University has received gifts for new buildings representing more than a million dollars. In addition to the two buildings at Bloomingdale, for which $500,000 was given some time ago by as yet secret benefactors, provision for a number of buildings for the College of Physicians and Surgeons has been made by members of the Vanderbilt family, in the sum of $350,000. The Vanderbilt clinic on Sixtieth Street will be enlarged by the erection of a building five stories high and 100 x 50 feet. Another building, 50 x 80 feet, will be erected on Fifty-ninth Street, east of the present main building.

Another important gift in connection with the medical school is one of $200,000 from Mr. and Mrs. William D. Sloane for the enlargement of the Sloane Maternity Hospital to nearly double its present size. Mrs. Sloane has also agreed to provide the additional money necessary for the maintenance and endowment of the enlarged institution. The new building will have a front of seventy feet on Fifty-ninth Street.

These new buildings will completely fill the Fifty-ninth and Sixtieth Streets fronts of the block occupied by the medical school, and will provide an equipment for Columbia far in advance of any other American medical school. The architects are already at work on the plans, and construction will be begun without delay. The property and the main building of the College of Physicians and Surgeons were given by the late William H. Vanderbilt; the clinic bearing his name was erected as a memorial by his children, while his daughter, Mrs. Sloane, endowed the maternity hospital.

Examinations for Diphtheria-Bacilli.—It is announced that the Laboratory of Bacteriology of the Philadelphia Polyclinic will make for physicians bacteriologic examinations in cases of suspected diphtheria. Sterilized swabs and blood-serum tubes, together with instructions for making the inoculations at the bedside, can be obtained from Mr. W. S. Leffmann, Clerk of the Faculty at the Polyclinic Hospital, on Lombard Street, above Eighteenth. The results of the examinations will be reported within twenty-four hours from the return of the tubes to the Laboratory.

Request for Addresses.—We have been asked to announce that many members of the Class of 1879 of the Jefferson Medical College of Philadelphia are desirous of having a class reunion on the occasion of the fifteenth anniversary of their graduation. To fulfil this end members are requested to communicate at once with the President of the class, Dr. Philip R. Koons, Mechanicsburg, Cumberland County, Pennsylvania.

Electric Railway Ambulance.—In the city of St. Louis a street-car, with electric motor attachments, and having an average speed of twelve miles an hour, has been fitted up as an ambulance, to be sent to all parts of the city in response to calls.

BRAIN-SYPHILIS: A REPORT OF SEVEN CASES.[1]

BY THEODORE DILLER, M.D.,
VISITING PHYSICIAN TO THE INSANE DEPARTMENT OF ST. FRANCIS' HOSPITAL; PHYSICIAN TO THE NEUROLOGICAL DEPARTMENT OF PITTSBURG FREE DISPENSARY.

THE study of brain-syphilis is always one of interest, chiefly because of the great variety and diversity of symptoms that may be noted in the affection and the endless difficulties encountered in the diagnosis. So eminent an authority as Professor H. C. Wood has stated (*American Text-book of the Theory and Practice of Medicine*, vol. i, p. 731) that "The diagnosis of cerebral syphilis during life is always a matter of inference." That is, I think, putting the matter too strongly. There are certain cases, I believe, in which one can feel as sure of his diagnosis as in any other form of intra-cranial disease.

Of the seven cases I am about to report (representing types of the disease), I feel very confident the first (Case I) was a genuine case of brain-syphilis. Case II had been diagnosticated by several physicians as one of paralytic dementia before the patient came under my observation. I debated in my own mind a long time on the matter of the differential diagnosis between paresis and brain-syphilis before I concluded that the case was one of the last-named disease. But even now I cannot feel certain of my diagnosis. Case III is one of brain-tumor, in which two features point to its being of specific character. Cases IV, V, and VI are somewhat similar and present features that point to syphilis rather than to any other affection. Case VII is undoubtedly syphilitic.

The more cases accurately recorded, the sooner will it be possible to formulate from the study of the literature certain general laws for diagnosis, and to test the value of those already promulgated. The number of cases already recorded is enormous, but we still need to study very many more. It is, perhaps, unnecessary to say that certain well-founded, well-tested laws of diagnosis are much needed.

When the structure and varied functions of the brain are borne in mind, it is not difficult to understand how the various syphilitic new-formations, and the consequences dependent upon them, found within the brain-case, produce such a great number and infinite variety of symptoms.

The syphilitic products are the results of specific inflammation, in all probability of bacterial origin. The vessels and the membranes, especially at the base, are affected by it. This specific inflammation leaves behind it general or nodular thickening of the membranes, gummata, arteritis (wholly or partly obliterating vessels), softening or patches of sclerosis (the results of obliterating arteritis). The degenerated vessels may rupture or thrombi may form within their roughened walls, or aneurysms may develop.

The common symptoms observed are headache, coma, somnolence, insomnia, dementia, and other psychic symptoms, paralysis, convulsions, polyuria, aphasia, and optic neuritis. Only one of these symptoms, *e. g.*, headache, may be present in a given case. Several of them may be present. The manner in which they appear, and the order and length of time they persist, vary greatly. It is, indeed, only by a study of these points that one is able to make a clear or even a provisional diagnosis.

Headache is perhaps the most common symptom. It was present in more than half of Gowers' cases (*Syphilis and the Nervous System*, p. 74). I have not found that it is confined to one part of the head. There is, however, in many cases, a marked tendency to periodicity, but I have not observed it so frequently as Gray (*American Journal of the Medical Sciences*, January, 1892, and *Nervous and Mental Diseases*, pp. 359–372). Headache may be the only symptom. In the absence of a specific history a positive diagnosis of syphilis cannot be made from this symptom alone, but in any case in which headache is severe and intermittent, and has lasted a long time, and has proved rebellious to ordinary treatment, it is certainly wise to suspect syphilis and administer specific treatment. When severe headache has existed for a considerable period, and is followed by some form of paralysis, or by convulsions or coma, there is much stronger ground upon which to base a suspicion of syphilis, especially when, with the appearance of these symptoms, the headache itself greatly abates or disappears. There may be hemiplegia, monoplegia, or more rarely paraplegia. Any of the cranial nerves may be paralyzed. The ocular nerves are very prone to paralysis; the facial is singularly exempt. The distinguishing feature of syphilitic palsies is that they are likely to be of gradual development, incomplete, and often rather suddenly improve or disappear. But paralysis, especially hemiplegia, may be sudden, although it is not likely to be so complete as the hemiplegia following hemorrhage. Paralysis slowly and successively involving different parts is strongly suggestive of syphilis. Hemiplegia in persons under forty-five years of age and over five years of age is likely to be syphilitic.

---

[1] A paper read before the Pittsburg Academy of Medicine, November 5, 1894.

Insomnia in connection with headache is a frequent symptom. A semi-comatose or somnolent condition is to be observed in many cases even when headaches are severe. Most writers agree with Fournier, that convulsions appearing for the first time in persons over thirty years of age, and not due to traumatism or other demonstrable cause, should raise a strong suspicion of syphilis, particularly if severe headache has immediately preceded the convulsive outbreak. Coma or a semi-comatose state of long duration, and which cannot be accounted for on other grounds, should give rise to a strong suspicion of syphilis.

Mental symptoms are exceedingly varied, but perhaps stupidity and general intellectual failure are most commonly seen. This dementia differs from acute dementia and senile dementia in being slow in onset and progress, or by the time at which it sets in. It differs from paralytic dementia in the absence of lucid intervals and extravagant delusions of grandeur, and by the fact that the course of the disease is of much longer duration and not characterized by the same tendency to remission. There is, however, much resemblance between the two; for example, there are to be seen in both dementia, general paralysis, inequalities of pupils, speech-alterations, and tremors. Indeed, I believe there are many cases on the border-line in which it is impossible to make a distinction. Many observers, it must be remembered, now believe that paresis is nothing more than a form of brain-syphilis. These cases of so-called paresis have been studied by the French, especially by Morel, Lavalle, and Belieres (*Syphilis and Paralysie Générale*, Paris, 1889).

Syphilis may act as the predisposing cause of any of the acute insanities. The form of the insanity is determined by the environment and inherent tendencies of the patient. From the symptoms that these insanities present it is impossible to say that syphilis is the cause, and it can, of course, be suspected only when there is a specific history or some other features pointing to syphilis.

Polyuria and optic neuritis are symptoms of value only in connection with other manifestations indicative of syphilis. Optic neuritis may be primary.

Much stress has been laid upon the diagnostic value of the therapeutic test. While it is often of value, it has, I am sure, been given too much weight. It not infrequently happens that a course of specific treatment will cause the partial disappearance of symptoms dependent upon organic brain-disease (*e. g.*, tumor) other than syphilis. On the other hand, it often happens that treatment fails to produce the least effect when the disease is unquestionably syphilitic. The more rapidly the symptoms disappear under specific treatment, all other things being equal, the more likely is the disease to be syphilitic.

A clear and unmistakable history of syphilis is, of course, of the utmost value; yet, from the fact that a person has had a hard chancre at one period in his life, it does not necessarily follow, as many physicians seem to think, that any symptoms he may suffer from in after-life are of syphilitic origin. It is, therefore, not enough to base a diagnosis of brain-syphilis upon the history of chancre. At least some symptoms should point to it. Of course, a person cannot suffer from brain-syphilis without having within him, either through inheritance or infection, the syphilitic virus. Yet there are clear cases of brain-syphilis in which there is no history of inheritance or primary infection, and, indeed, in which both are positively denied. I believe, with Gowers, that there are many more such cases than is commonly believed.

Indeed, so unsatisfactory is the history of syphilis that I attach less and less importance to it, although of course the intelligence of the patient has much to do with the value of the specific history. There are some cases in which I believe it is best not to inquire into the matter at all. The mere question may cause heart-burnings or family discords that may last for years; for very often the physician is prepared to give anti-syphilitic treatment whether chancre is admitted or denied. These elements of uncertainty and unpleasantness about the specific history make it all the more desirable to secure, if possible, data upon which to base a diagnosis in the absence of a specific history. As the result of my own experience and a considerable search through the literature, I concur with Gray (*Mental and Nervous Diseases*, p. 369) in stating that we should suspect intra-cranial syphilis if there are present:

1. Quasi-periodic headache that returns at a certain time in the twenty-four hours, and is most frequent at or toward night, and less frequent in the afternoon or morning.

2. Paralytic or convulsive symptoms that have been preceded by this characteristic headache and insomnia, when the headache and insomnia have suddenly ceased upon the supervention of the paralysis or convulsion.

3. Symptoms indicative of a lesion at the base of the brain, preceded or not by the characteristic headache and insomnia.

4. Convulsions in the adult which have not been preceded by convulsions in infancy, and are not of traumatic or nephritic origin, or due to pregnancy, or occur in an individual subject to migraine.

5. Hemiplegia in an adult under forty years of age, even when there has been no preceding headache and insomnia.

6. A comatose condition extending over days or weeks, not traumatic, meningitic, diabetic, nephritic, or from typhoid fever.

To these I would add :[1]

7. Paralytic symptoms that are incomplete, slow in onset, unaccompanied by unconsciousness, and which quickly improve or disappear.

In the cases to be related, illustrations of all these laws excepting those pertaining to coma and convulsions will be found. I believe the most important diagnostic point is *the peculiar headache, when it has preceded paralytic, convulsive, or mental symptoms.* This feature is illustrated in all but one of these cases.

CASE I.—J. C. D., aged forty-two, single, a manufacturer of boats, has never drunk heavily, but has worked hard all his life. He contracted syphilis in 1877, and had pneumonia in 1878. After the syphilitic infection he had sore-throat, skin-eruption, and his hair came out. He went to Hot Springs to get specific treatment. About two years ago headaches set in, which became of daily occurrence; they were frontal and for the most part very severe. After three months of very great suffering, they left him. After this they frequently reappeared in great severity, but each attack lasted only a short time. Very soon after the appearance of this headache he suffered from a severe attack of influenza, upon recovery from which it was noticed that there was some bulging of the eyeballs. A few days later a little stammering and hesitancy of speech were noted. Then he became a little dull mentally, and memory for recent events became impaired. Generally speaking, he grew worse steadily for three or four months, and then deteriorated very slowly until the time I first saw him, November 11, 1893, except that the mental symptoms had been increasing rather rapidly for three weeks immediately prior to that date.

On November 11, 1893, the examination showed a large man, 5 feet 10 inches in height, weighing 210 pounds. He has weighed the same for ten years past; his appetite was good; he slept well; the bowels were regular. The dynamometer with the right hand registered 80, with the left hand, 95. The knee-jerks were normal; he had a slightly ataxic gait, not increased when the eyes were shut. Mentally he was quite dull and lethargic; speech was slow and halting, with considerable slurring of words. Besides, there was loss of memory for certain words which he wished to use—evidently a genuine aphasia. He was having no headaches, and no delusions or hallucinations. He was still able to attend to some business and travel alone from his home, some thirty miles distant, to this city.

I ordered ʒj of potassium iodid daily, divided in three doses, besides mercurial inunctions. The mercury was discontinued in about two weeks. The iodid was increased steadily for about one month, when he was taking 300 grs. daily, which amount was given for four months. On December 4th he was duller mentally. On December 6th he was taken to St. Francis' Hospital, and had a severe (malarial) chill. On December 29th there was slow but steady improvement. On January 9, 1894, he was a little worse. On January 14th he was growing steadily worse. The saliva was running from his mouth, and he could scarcely articulate a single word properly. It was doubtful whether he knew me. He was very noisy the night before, and dementia was profound; the left pupil was larger than the right. On January 17th there was no change. On February 1st there was steady improvement since the previous note, and on February 17th the improvement continued. On March 12th he was improving constantly, the memory was quite good; there was no aphasia, but speech was still somewhat slow. On April 2d he was discharged, practically well. I directed him to take 100 grs. of potassium iodid three times a day for the first week in each month during the remainder of the year. I saw him September 15th for the last time. He continued to remain well and to follow directions explicitly as to taking the iodid.

CASE II.—J. Z., aged thirty-seven, married, but whose wife has never borne children, denied syphilis. Mr. Z. led an active life as a politician; he was a cheerful, easy-going man, and always enjoyed, up to the time of the present trouble, excellent health. About four-and-a-half years ago it was noticed that he was getting somewhat careless in the discharge of his duties; that his judgment was not so good as formerly; and that he was becoming somewhat careless in the use of money. At this time and for some weeks previously he had been troubled much with headache. These mental defects increased slowly as months went by. He lost money by going into business schemes that were not considered sound, and yet which were by no means wild. He was compelled to give up business and political work; then he grew emotional; cried occasionally when vexed, and complained a good deal about trifling matters. He was sent to a sanitarium, where his trouble was diagnosticated as paralytic dementia. Returning to the city after a couple of months, he made a further business venture, but was again unsuccessful.

I saw him for the first time about six months ago. At that time he was cheerful and talkative; his memory was good, both for remote and recent occurrences; his dress was neat and tasteful. A careful search failed to discover any delusions. His speech was slow, somewhat halting, and there was some evident general mental failure. Several times, when contradicted, he seemed on the point of breaking into tears. He could not spell Pennsylvania correctly. In attempting to repeat "National Intelligencer" he would say "National Intelliger." His handwriting was unchanged.

---

[1] I wrote to Dr. Gray concerning this point, and he replied: "I believe your seventh point about intra-cranial syphilis is a valuable one. I had never thought of it before you wrote, but your speaking of it calls up to my memory numerous cases in confirmation of your belief."

In the spring of this year, shortly after I first saw him, he was removed to St. Francis' Hospital, where he has remained practically unchanged up to the present time, having been three months of this time under my constant observation. He gets along very well in the hospital, constantly recognizing that he is a sick man and desiring relief. He is prone to magnify trifles, *e. g.*, was very much worried several times when he had a slight diarrhea ; cried because medicine did not come as soon as he expected ; cried several times when articles belonging to him were either mislaid or appropriated by other patients. He often complained of a certain distress in the head, the exact nature of which was never made clear to me. Habits of personal neatness remained unchanged. Dr. Edsall recently made an ophthalmoscopic examination, but found no changes in the eye-grounds.

Both of these cases bear much resemblance to paralytic dementia. The first may, I think, be distinguished from it by the clear history of syphilis; the violent headache that preceded the mental symptoms ; the nature of the mental symptoms themselves; the absence of expansive delusions; and lastly, the remarkable improvement under specific treatment, which has for months been maintained.

The second case is one much more difficult of diagnosis. It may even now be considered a debatable question, but I incline to the view that the case is one of intra-cranial syphilis, because of the headaches, the slow progress of the case, the absence of characteristic delusions of grandeur, the tidy habits of the patient, the fact that he uniformly recognizes that he is a sick man. There is here no syphilitic history to aid one in the diagnosis. Cases such as this have been, by Fournier and others, denominated pseudo-general paresis. Time will determine whether I am right in believing it to be such, or whether the case is really a slow, atypical form of paralytic dementia.

CASE III.—P. X. was seen September 9, 1894, referred to me by Dr. J. A. Lippincott, aged forty-seven, single, a university professor, small in stature and of a nervous temperament. Since the age of fourteen he has led a student's life, has drunk more or less all his life, drinking excessively in 1892. No specific history was obtainable. In May, 1892, Dr. Lippincott examined his eyes and found paralysis of the external rectus of the right eye. Both eyes were myopic and astigmatic. Both discs were swollen, with some tortuosity of the vessels. The right eye moved only a quarter of an inch beyond the center outward. During the summer of 1892 he was troubled a good deal by this diplopia. Some peculiarity in his gait was noticed about the same time. He would stagger, and, at times, have a tendency to go to one or the other side. About the same time the diplopia appeared he began to suffer from paroxysms of headache. Headache, diplopia, and uncertain gait have continued up to the present time. He himself attributed the uncertain gait to his double vision.

Last winter (1893-94) considerable improvement took place, which, however, lasted only a short time. Headaches returned with greater severity than ever, and diplopia annoyed him exceedingly. For a while he veered to the right side in walking, afterward to the left side. The gait was shuffling, the feet wide apart. Vision began to leave him rapidly. By February (1894) it had entirely faded from the right eye, and by the middle of August from the left. A month ago Dr. Milliken, of Cleveland, examined his eyes and reported almost complete atrophy of both optic nerves. About this time he was having, and now has, from four to eight paroxysms of headache, each lasting about ten minutes, in the twenty-four hours. In about one of six attacks he vomits. This vomiting is always sudden and is preceded only by a momentary feeling of nausea, and apparently stands in no relationship to previously-ingested food. The head-pains are frontal and occipital. In many attacks the frontal pains alone are present. When there is occipital pain there is always more severe frontal pain at the same time. It is alike on both sides. On August 16th and September 18th he suffered from attacks of syncope, lasting about fifteen minutes, preceded by vomiting. There was delirium and more or less mental confusion for an hour or two following these attacks. Examination September 18, 1894, showed that the man could not carry the right margin of the cornea of the right eye more than half the distance to the external canthus. The pupils were widely dilated, and there was total blindness of both eyes. There was general weakness, but no local paralysis; the dynamometer showed—R., 48, L., 35. Pain-sense was present, and there was general dulling of tactile sensation. Hearing in the right ear was greatly impaired. (This has been so for many years.) Taste was very defective, and he could not distinguish salt from sugar, but he recognized vinegar. It has been noticed for several weeks past that apparently all foods tasted alike to him. The sense of smell was almost absolutely abolished, and he was utterly unable to distinguish a number of common odors. The patient was unable to say just when the sense of smell left him, but stated that it left the right side before the left. Both knee-jerks were exaggerated, the right distinctly more than the left. No mental defect was appreciable. On September 29th his family physician wrote that there was some little improvement, and the headaches not so severe or frequent.[1]

Headache, optic neuritis, followed by atrophy, and vomiting, point to the presence of intra-cranial tumor. The sixth-nerve palsy on the right side, existing from the beginning of the trouble, and the absence of the sense of smell, which developed first on the right side, led me to localize the growth at the base of the brain on the right side near the median line, about the junction of the frontal and temporal lobes. The fact that vision faded from the right eye for several months before it did from the left would also favor this view.

---

[1] His condition has since deteriorated very much.

There is no history of syphilis. I can only suspect that the growth is a gumma from the early appearance and violence of the headaches and the belief that the growth is situated at the base of the brain.

CASE IV.—W. B., aged eight years, was seen September 29, 1894, referred to me by Dr. Joseph Dickson. His parents, brother, and sister were healthy. No specific history was obtainable, but there was a suspicious appearance of the teeth. The boy had always been healthy up to nine weeks before, when he complained vaguely of not feeling well. A doctor was called who prescribed for him. The lad got better, although not quite himself, and remained so for two weeks, when he returned from play one day saying he was sick, but complained of no special symptoms (this was seven weeks before). That night he awoke with a bifrontal headache so severe that he cried out. It lasted half an hour, when he went to sleep and slept until morning. Immediately upon awakening he complained of severe frontal headache. Every day thereafter for three weeks he suffered from frontal headache from morning until night. No other symptom was present. He was free from headache and slept at night during this period. At the end of three weeks the headaches left him, and, excepting two attacks, did not return in the following four weeks. Just at the time the headaches ceased his mother noticed that there was some loss of power in the left leg. A week later it was noticed that the left arm was losing power, the paralysis in the leg having, in the meantime, increased. The loss of power in the arm increased rapidly, so that two weeks from the onset it was absolute. The paralysis of the leg proceeded more slowly, and for the past two weeks has remained stationary. At the time the arm-palsy began, the boy, for the first time, misnamed objects and dropped words and letters in talking, his speech being halting and slurring. About the same time he became dull, listless, lethargic, and very soon afterward sight began to fade from both eyes. These symptoms have increased up to the present time. His mother states he has grown much worse even in the past two days.

On the day I saw him the paralysis of the left side was present as noted; but there was some evident weakness of the right side too. The boy was unable to walk; his face was dull and he was listless; saliva dribbled; his pupils were dilated; sight was almost absent; the knee-jerk was present, but sluggish. Dr. Edsall found distinct optic neuritis in both eyes, more marked in the left, and vision was almost gone. Inunctions of mercury and scruple doses, t. d., of potassium iodid were ordered.

As I write I have just received word from his family physician, Dr. Jamison, of McDonald, saying that there has been steady improvement since I saw him.

Here we have an incomplete hemiplegia of slow onset; aphasia and great mental hebetude, immediately preceded for three weeks by agonizing headache. A syphilitic history is wanting. Specific treatment causes prompt and unmistakable improvement. That these symptoms were due to congenital syphilis can scarcely be doubted.

CASE V.—October 9, 1894, I saw Mrs. M., in consultation with Dr. Larimer; her age was forty-five; she was married; had no children; she had a miscarriage sixteen years ago, eight years after marriage. She has never been in robust health, but got along fairly well. Her present illness dates from about January 1, 1894, at which time she began to suffer from headaches. These were more or less periodic (worse toward night) and much of the time very severe, even agonizing, causing her to cry out. She was scarcely free from them a single day. A couple of months ago a boil appeared one-half inch below the external canthus of the left eye. This subsided after a time, but remnants of it are even now apparent. These were the only symptoms till about seven weeks ago, when her left arm began to lose power. At the same time the headaches left her. This loss progressed evenly for about one week, at the end of which time the member was completely paralyzed and has remained so ever since. A few days after this paralysis in the left arm had appeared the left leg began to lose power, and the loss progressed for about ten days, since which time the leg has slowly regained power up to date, October 9th. Yesterday morning (8th) she felt a numbness or tingling in the fingers of the right hand. This morning there was a distinct and marked loss of power in the right arm (not absolute), and at the same time the patient, for the first time, experienced difficulty in talking, not being able to utter more than a few words, and miscalling objects and persons; she evidently knew what she wished to say, but could not utter words for the idea, giving affirmative and negative by shakes of the head.

Examination the evening of October 9th showed that the woman seemed sixty instead of forty-five years of age; her hair was white; and there were redness and puffiness about the left eye. There was almost complete aphasia. She apparently understood what was said; pain-sensation was present; she felt the touch of a finger on various parts; there was no discoverable sensory disorder; the left hand was puffy and white; the fingers closed; the arm contracted at the elbow and wrist, and paralysis was absolute; she could move the right arm in all directions, but there was a marked loss of power; she walked with a little assistance, dragging the left foot heavily. We prescribed 15 grains of potassium iodid, t. d., to be increased 1 grain a day, and mercurial ointment each morning. On the 10th the aphasia became absolute; on the 13th she began to lose power in the right leg, and this loss increased until the 16th, when it became absolute. During the last twenty-four hours there has been some appreciable regain. No special change was noted on the left side. She evidently knew what was said, but would nod head for negative and affirmative. She refused to put out her tongue when asked, simply opening the mouth, but to-day she protruded it, although a second time she would not do so. (Hysterical element.) She made known calls of nature by restless movements in bed. She objected strongly to the iodid. Dr. L. stopped it two days ago and gave her strychnin.[1]

Here we have, as in the preceding case, paralytic symptoms of slow onset unaccompanied by unconsciousness, preceded for months by severe headaches. Dr. Larimer and I both thought it best not to search for a syphilitic history in this case. Specific treatment has as yet effected no improvement; notwithstanding this I feel pretty sure that this is a case of syphilitic arteritis and meningitis.

For a time I feared softening was taking place. The shifting nature of the paralysis and apparent hysterical symptoms are interesting features. Hysterical symptoms may, it is well known, be engrafted upon grave organic disease (see cases reported in *Medical Record*, 1894, by Dr. Philip Zenner and myself). Pure hysteria can be thrown out, I believe, by the facts that trophic changes and contractures are present in the left arm; that aphasia appeared simultaneously with the right-arm palsy, and that severe headache preceded for months the paralytic symptoms.

Case VI.[2]—A. G. came to the Pittsburg Free Dispensary May 15, 1894. His age was forty-one; he was married and a tanner by trade. Eleven years ago he had a sore on his penis, which he believed was a chancre. On May 20, 1893, while at work, he became giddy; then half an hour later he suffered from a severe pain across the forehead. Consciousness was preserved, but he lost vision on the left side. He walked home from the tannery that night alone. Four days later, paralysis of the left side slowly appeared and increased. For seven weeks the paralysis was so severe that he could not walk. He has never lost sensation in the paralyzed parts. The field of vision was normal; the grasp of the left hand is one-fifth that of the right. The paralysis was more marked in the arm than in the leg; the face was slightly drawn to the right side, and there was atrophy of the paralyzed muscles; there was general dulness of tactile and painful sensibility; the patellar tendon-reflex was increased on the affected side.

The history of syphilis, the slow onset of the hemiplegia, with preservation of consciousness, and the age of the patient, are points that led me to believe that the symptoms were of syphilitic origin. The apparent loss of vision in the left eye was probably due to a left hymonymous hemianopsia. Antisyphilitic treatment proved ineffective.

Case VII.[1]—A man aged thirty nine was referred to me by Dr. Robeson, November 12, 1894; he was married and had always enjoyed good health. Five years ago he had a chancre, followed by a "reddish" skin-eruption. Three years ago, for a period of four weeks, he suffered most agonizing headaches, which would come on about four o'clock in the afternoon and last nearly all night. One year ago last spring, while apparently enjoying excellent health, he was seized with a general convulsion which lasted one hour, during which he was unconscious, frothed at the mouth, and bit his tongue. The second day after the fit he resumed his work and continued at it, in his apparent usual health, until April, 1894, a period of one year. At this time he was suddenly seized with an attack of vertigo, which lasted twenty minutes, and during which he was "numb" on the left side. A short time later, an attack of left-sided "numbness," lasting nearly a day, occurred. A couple of weeks later (June 1st) he staggered in walking. At the same time memory and general intelligence began to fail, *e. g.*, an hour after dinner he would ask for the meal, forgetting he had eaten. He became increasingly drowsy, and he would sleep after dinner, at his desk in his office. He would go to sleep at almost any time or place. Toward July 1st he would sleep almost the whole twenty-four hours of the day. At this time delusions and hallucinations appeared About the middle of July he was seized with another convulsion, immediately following which he was confined to his bed for six weeks, being in a condition of stupor; much of the time he did not know his wife. During all the six weeks the stupor lasted he complained very often of severe headache, and during this time he had six convulsions. There was almost constant conjugate deviation of the eyes to the left. After he had been in bed five weeks (during which time his bowels had not been moved) the homeopathic physicians who had been attending him pronounced the case entirely hopeless, diagnosticating paresis.

At this time the patient's wife was counseled by a nurse living in the neighborhood to supplement the diluted Hahnemann treatment by a large strong rectal injection of glycerin and water. This was done, and according to the wife's statements, the results were not homeopathic, for a mass of matter came away from the bowel so offensive in character that it became necessary to open the windows and disinfect the room. For one week afterward there was an almost constant flow from the bowel, and *pari passu* improvement in symptoms, so that at the end of the week the change was marvellous, the man declaring that he was almost ready for work. The six weeks of stupor are now a blank in his memory.

Upon getting out of bed he noticed that he was blind on the right side. With this exception, he thought himself well until two weeks ago, when he began to lose power on the right side of the face, so that he could not close the eye. About the same time, or a little before, he would occasionally see double. This trouble increased up to the time I saw him.

---

[1] Since this was written the patient has greatly improved.

[2] Reported in the proceedings of the Allegheny County Medical Society.

[1] The report of this case has been added since the paper was read.

Examination (November 12, 1894) revealed right homonymous hemianopsia (accounting for the right-sided blindness), total paralysis of the sixth nerve on the left side (accounting for the diplopia), and marked although not complete paralysis of the right facial nerve. No changes in eye-grounds, according to Dr. Robeson, were found. There were no other symptoms worthy of note.

He has now (November 19th) been on vigorous antisyphilitic treatment for two weeks, and shows very marked improvement. The sixth-nerve palsy and consequent diplopia have almost entirely disappeared, while the improvement of the seventh-nerve palsy has been almost equally marked.[1]

This case presents almost the entire catalogue of symptoms seen in intra-cranial syphilis, and lends force to nearly all of Gray's indications. To recapitulate briefly: There were chancre, severe headaches with marked periodicity, convulsions, somnolence, psychic symptoms, stupor with headaches, so to speak, protruding through it; cranial-nerve palsies (one of which was incomplete) of slow onset, numbness, and conjugate deviation of the eyes.

The wide range and inharmonious grouping of symptoms in this case are of themselves features of diagnostic value.

On the whole the case is more instructive than any of the others described. I think no one will question that it is one of brain-syphilis. A diffuse arteritis and gummatous meningitis affecting especially the base would most plausibly account for the symptoms, for they could not have been due to a single lesion.

The prognosis is most favorable when symptoms are produced by active inflammatory syphilitic exudate. In the words of Gowers (*op. cit.*, p. 97), "The tissue-formation of syphilis is the element that can be influenced with the most frequency, with the most certainty, and in the greatest degree." It must be borne in mind that the syphilitic inflammation causes secondary changes, *e. g.*, indurations, sclerotic patches, and softening. Many of these are almost wholly incurable and entirely beyond the reach of anti-syphilitic remedies. A severe syphilitic lesion within the brain-case leaves behind cicatrices, scar-tissues, representing a loss of some tissue and impairment of others. Similar after-effects are seen in the skin, the liver, and other organs. For these reasons one would certainly be unwarranted in giving a uniformly favorably prognosis in cases of undoubted intra-cranial syphilis. As a matter of fact, some cases are not at all amenable to treatment. Strictly speaking, all cases are incurable in the sense that we can never drive the virus out of the system. But, for all practical purposes, many cases are relieved of their symptoms with wonderful rapidity under specific treatment. On the whole, the prognosis is probably more favorable than in any other organic brain-disease. "Syphilitic hemiplegia has not a much better prognosis than hemiplegia from other causes," says Dana (*Text-book of Nervous Diseases*, p. 401). Case VI illustrates this point. Case II received a long course of iodids without the least benefit. Cases I, IV, and VII illustrate in a striking way the favorable results of treatment. Cases III and V have been under treatment too short a time to enable me to form an estimate of the value of the treatment.[1]

My views concerning the treatment are in accordance with those of most American neurologists, viz.: that in potassium iodid in large doses we have our chief remedy. When the small doses of the English, Germans, and French prove inefficient, I believe the large doses given in this country will often effect great improvement. Generally speaking, it it is best to begin with a dose of ten or twenty grains, and rapidly increase either by a grain each day or a grain each dose until iodism occurs, or the symptoms are yielding, or a certain maximum has been reached. Seldom is anything to be gained by exceeding one ounce in the twenty-four hours. In most cases I do not exceed 360 grains in a day. I have, however, given as much as an ounce-and-a-half, and Dana (*Text-book of Nervous Diseases*, p. 402) has known 500 grains to be taken three times a day with benefit. Hirt, a careful German writer, who reflects the views of his countrymen, speaks of the value of administering the iodids energetically, and mentions two drams as a maximum daily amount. (*Diseases of the Nervous System*, p. 659.) This dosage is, I am sure, often inadequate.

There is nothing to be gained and something to be lost by keeping up the administration of large doses of iodids indefinitely when there is no sign of improvement. If symptoms do not yield in three or four months, the drug should be discontinued, for it may have a harmful effect in depressing the general health. When symptoms have yielded to the drug it should also be discontinued for a time. To forestall a subsequent outbreak of the disease it is much better to administer the drug for short periods from time to time than to keep up its use continuously for months, even in small doses. It is a good plan to give it for a week in each month or for two or three weeks, four times a year. A practical little point in the administration of the iodid is to give it well diluted in water. Given in this way it is more readily absorbed from the stomach and is less likely to produce gastro-intestinal irritation.

What place has mercury as a remedy against these late lesions of syphilis? I believe, with the majority, that it is not nearly so valuable as the iodid, but I would, by no means, go as far as Gray in practically discarding it altogether. (*Nervous and Mental Diseases*, p. 370.) Wood, on the other hand, uses it "more and more" (*op. cit.*, p. 732), following it up after a time with the administration of potassium iodid for the purpose of eliminating the mercury.

---

[1] Excepting the hemianopsia not a symptom remains.

[1] Case III has become much worse, while Case V is greatly improved.

It is my custom, in beginning treatment, to give mercurial inunctions along with the iodid for a week or two, and then drop them, continuing the iodid alone in the ascending doses. In cases in which there seems to be danger to life, the mercurials should be given vigorously at the start and maintained until slight salivation is produced. Whether there is any special virtue in the much-vaunted hypodermic method I am unable to say, not having any experience in this method; but I must confess that the plan does not recommend itself to me.

The administration of the iodids and mercurials does not, by any means, constitute the only means to be employed in brain-syphilis. The general condition of the patient must be studied as carefully as in any other disease. Baths, electricity, tonics, and massage may be indicated. It is desirable in all cases that the patient should have rest and be freed from cares and anxieties as far as possible. Foreign travel or sojourn from home may be recommended for some.

WESTINGHOUSE BUILDING.

THE EFFECT OF THE LOCAL APPLICATION OF GUAIACOL IN THE REDUCTION OF THE TEMPERATURE IN TYPHOID FEVER.

BY H. G. McCORMICK, M.D.,
OF WILLIAMSPORT, PA.

IN a conversation I had last spring with Dr. J. Solis-Cohen regarding a case of pulmonary tuberculosis with a high temperature, he suggested the use of guaiacol locally applied for its reduction as a remedy that had proved useful in his hands.

When I entered upon my term of service as attending physician to the Williamsport Hospital, the first of September last, I determined to give this remedy a good and fair trial in the reduction of temperature in typhoid fever. I had it applied 230 times in the hospital and 43 times in private cases, making 273 times it was applied under my direction in three months. These applications were made to 12 different persons, 7 males and 5 females, making an average of about 24 applications to each person. The greatest number of times it was applied to any one person was 70, and the least number of times it was applied was once; the largest dose used was 25 drops, and the smallest dose used was 2 drops; the greatest reduction of temperature was from 106.8° to 101°, by the application of 5 drops, in the case of Mrs. Horton, with a corresponding reduction of the pulse from 136 to 110 per minute. Again you will notice in the same case, by applying 5 drops on the same day when the temperature was 106.2°, with a pulse of 148, it was reduced in one hour to 102°, and the pulse to 120 per minute. This patient, as you may see by consulting the special reports, was unusually susceptible to the action of this drug, as the application of 2 drops when the temperature was 103° and the pulse 130, in one hour and thirty minutes reduced the temperature to 100.4° and the pulse to 120, while in the case of James Hill 20 drops were required to reduce the temperature from 104° to 98.4° in three hours and fifteen minutes.

I show you a large number of special reports of the cases in which guaiacol was applied, and which may be useful in showing not only its effect on the temperature, but also the effect on the pulse and respiration. You will observe that within thirty minutes after the application there was a fall in the temperature, and in most cases there was a corresponding reduction in the number of heart-pulsations per minute. The method of application was as follows:

The right iliac region was thoroughly cleansed with soap and water, and, after being dried, the guaiacol was slowly dropped upon the part and thoroughly rubbed in with the hand for from ten to fifteen minutes. The part was then covered with oiled silk. The only preparation used was that prepared by Merck, and it did not fail in a single instance to produce the desired result. Any other point would probably be as good for its application, but as it was as near the seat of the disease as I could possibly get, and the ease with which it could be reached and covered with the oiled silk without in any way disturbing the patient, made me select this point for its use.

The effect of guaiacol lasts from three to four hours, and the more often it is used the greater the effect. I observed a number of chills from the sudden reduction of temperature, but after I became more accustomed to its use the chills were much less frequent. If it can be avoided, the temperature should not be reduced below 100°, which can easily be regulated after the applications have been made a few times, care being taken to commence with a small dose, say 10 or 15 drops. I have never found it necessary to use the large doses of 40 or 60 drops as employed by Dr. DaCosta.

It has been suggested that by this rapid reduction of temperature there is danger of producing congestion of some of the internal organs of the body. I have not seen a single unfavorable symptom (except the occasional chill) follow its use.

All of my cases recovered. There was but one case of pneumonia-complication, and this could in no wise be attributed to the guaiacol, as it came on six days after the last application had been made. Sweating nearly always followed the application, being more severe when the reduction of temperature was sudden than when it was more gradual. No marked depression followed; the pulse was lessened in frequency and decidedly improved in strength.

No irritation of the skin followed when the guaiacol was used alone, and patients never objected to its use. The disagreeable odor that has been described by some as being objectionable to patients was never referred to by but one, and then only on the first application.

I used guaiacol and eucalyptol combined in the proportion of one of the former to two of the latter a number of times, but believe I had better results with the guaiacol alone. Besides, eucalyptol produces decided irritation of the skin, and in no way adds to the efficacy of the guaiacol.

This drug when applied to a person having a normal temperature produces no effect either upon the general condition of the individual or upon his temperature, as shown by an appended chart.

When I was following these investigations I had no knowledge of guaiacol having been used locally for the reduction of temperature in typhoid fever, but on looking over the literature of the subject I found that Dr. DaCosta used it in a few cases in the Pennsylvania Hospital last spring.

It is asserted by therapists that guaiacol is eliminated by the lungs and kidneys. In my cases treated with it repeated examinations of the urine were made by the resident physician, with negative results so far as the finding of the drug was concerned. It was at times noticeable on the breath.

In the carrying on of these investigations I received material aid from Dr. H. C. Frontz, resident physician, to whom I wish to return my thanks.

In summing up this question I feel convinced of the following facts:

1. That guaiacol when locally applied is certain to reduce temperature.
2. That with the care that a physician should always use in the administration of drugs, it is absolutely safe.
3. That chills will not occur if the temperature is not reduced below 100° Fahrenheit.
4. That no deleterious effect is produced upon any of the organs by its use.
5. That it is easy to apply, and can be used by any one competent to nurse a typhoid-fever case.
6. There are no depressing effects following an intelligent use of the drug.
7. That by continued use the dose can be gradually lessened.
8. That it is far superior to the cold bath; that it can be used by one person; that no appliances are necessary for its use that are not obtainable in every house; that it is much more pleasant to the patient; that it is fully as effective; that patients are not subjected to the danger of moving, and they offer no resistance to its use.

I have thoroughly tried the bath and cold packs, and I know they have proved very efficacious in many cases, but with my experience with guaiacol I have no desire to return to either of them.

FURUNCULOSIS OF THE EXTERNAL AUDITORY CANAL.

BY S. MACCUEN SMITH, M.D.,
CLINICAL PROFESSOR OF OTOLOGY IN THE JEFFERSON MEDICAL COLLEGE;
SURGEON IN CHARGE OF THE EAR AND THROAT DEPARTMENT
OF THE GERMANTOWN HOSPITAL, PHILADELPHIA.

ATTACKS of circumscribed inflammation in the external auditory canal, known as boils or furuncles, are of such frequent occurrence, and cause the sufferer so much pain and inconvenience, that the necessity for a more extended recognition of their existence, and especially a knowledge of the efficient means we have for their relief, has induced me to submit a few practical hints upon their treatment.

Notwithstanding the fact that furuncle of the external meatus is one of the most common ear-affections that the physician is called upon to treat, the condition is, nevertheless, often difficult to recognize and troublesome to combat successfully. Here, as elsewhere, the furunculous inflammation is limited to a small area, and has a strong tendency to the formation of pus, owing probably to the fact that the canal is abundantly supplied with excretory glands, and when inflammation is once inaugurated it usually runs an uninterrupted course to the stage of suppuration.

Inflammatory diseases of the auditory meatus are plainly and properly classified as being either acute or chronic, circumscribed or diffuse. They may involve simply the integument, or may extend more deeply into the subcutaneous structures, and implicate both the periosteum and bone.

The lining membrane of the external auditory canal is a continuation of the integument covering the auricle, being, however, considerably modified as it reaches the osseous meatus. As the membrana tympani is approached, this same integument undergoes still greater changes, and forms the outer layer of the drum-head. Notwithstanding the striking alterations observed in the appearance of the skin of the auricle and of the auditory canal, as in contrast to that noteworthy modification each undergoes to constitute the outer layer of the membrana tympani, yet neither the drum-head nor the skin of the auditory meatus can be spoken of or treated as a mucous membrane, any more than it would be proper to consider the integument of the auricle as such. Mention of this is made at this time for the reason that some writers have described certain affections of the canal under the head of "catarrhal inflammation;" but, as the word *catarrhal* can only be applied or used in connection with the diseased condition of a *mucous membrane*, it is quite impossible for the external auditory canal to be the seat of such an inflammatory process, inasmuch as the canal is covered with *integument* and not with *mucous membrane*.

It has already been definitely established that the great majority of pathologic conditions are traceable to the destructive action of disease-germs, and that pus-formation does not occur without the presence of pyogenic microörganisms. The researches and subsequent claims of Löwenberg likewise demonstrate that these microörganisms play an important part in the etiology of furunculosis of the auditory meatus. If then the disease in question is the result of a specific germ-poison, it is reasonable to assume that our failure to treat successfully some of these cases within a reasonable time is due to the fact that the remedies employed for their relief are but feebly germicidal, and, therefore, insufficient to destroy the infecting bacterium.

Those actively engaged in this line of work in a large dispensary and hospital service must at times have been impressed with the thought that boils of the external auditory canal occur epidemically. Usually, of course, these cases are sporadic; but at certain periods of the year (notably in the spring and fall) they are seen in large numbers, and come so often from a particular locality, that we are inclined to believe them not only epidemic, but also infectious and contagious. During the fall of 1890 I saw 117 cases of boils of the meatus, sixty-two of which came from a locality embraced within an area of about one square mile. Forty-six of this number were males and sixteen females. Fifty-one were suffering at the same time from an acute attack of influenza, but without severe constitutional disturbances; while eleven showed no apparent illness whatever. As to the situation of the boils, fifty-two were in the cartilaginous meatus, four in the deep osseous portion, and six at the extreme outer end of the canal.

When the direct cause of an aural furuncle is obscure it has been customary to attribute it to an impairment of the general health, which in many cases is quite evident and conclusive. However, it is interesting to note the large percentage of apparently healthy people we find suffering from boils of the external meatus; furthermore, in these otherwise hardy patients, it is the exception to find any that have been troubled with boils on other parts of their person. Löwenberg, who was the first to point out the parasitic nature of aural boils, has definitely proved that furunculosis can be artificially produced by rubbing sound skin with staphylococci. We have in this demonstration, therefore, a plausible explanation of the cause of aural furuncle in persons who are otherwise enjoying good health, especially when the origin cannot be traced to a chronic suppurative otitis media, the introduction of bacteria into the canal through the use of dirty plugs of cotton-wool, or to direct mechanic or chemic irritation. The initial etiologic element, is, therefore, shown to be infection by the direct entrance of a staphylococcus beneath the skin, through an abrasion or by way of a hair-follicle or ceruminous gland.

In the same manner we have reason to believe that the public phonograph is liable to become a source of aural infection of no small proportions, as it has become quite common for a community to use the phonograph placed in a conspicuous place for their amusement. The hard-rubber ear-pieces are seldom cleansed, and, being passed from one individual to another, it can readily be seen how either the public phonograph, or other similar instruments, may be the means of conveying infectious material from diseased to healthy ears.

TREATMENT.—Many physicians have doubtless been annoyed with the stubborn resistance of aural boils and their failure to yield to the various therapeutic agents employed for their relief; moreover, the repeated recurrence of this affection has been embarrassing to the physician and vexatious to the suffering patient. Many lines of treatment, both local and general, have been suggested for their relief; but unless such therapeutic measures have as an object the destruction of disease-germs they must in a measure continue to be unreliable and disappointing. The auditory canal, and in fact the entire ear, presents many obstacles to the attainment of strict asepsis in the treatment of its various diseases. Were it possible to overcome these difficulties entirely we could then expect these obstinate affections of the ear to be as amenable to treatment as when located in other organs. Much progress, however, has recently been made in the employment of antisepsis in this locality, and we are now enabled under proper precautions to operate with almost immunity on parts of the ear that heretofore would have been regarded as most hazardous.

In this, as well as in other similar ailments, the important object of treatment is the immediate relief of suffering, together with the limitation, modification, or abortion of the inflammatory process. Our ability to accomplish one or more of these purposes will largely depend on the stage the disease has reached before treatment is begun, as well as the efficiency of the remedies employed for its relief.

The treatment generally accepted for furuncle is very simple, and consists in an incision through the boil, dividing the periosteum down to the bone. This procedure, however, is usually more applicable to boils that are well advanced. Our treatment will serve a much better purpose if the case is diagnosticated at an early period, when an attempt can be made to abort the incipient boil. We know that many inflammatory processes might be aborted or limited in their destructive action if they could be subjected to local antiseptics that were not only powerful germicides, but at the same time non-poisonous and non-irritant. In the compound known as camphor-phenol, which is composed of fifty-five per cent. of camphor and forty-five per cent. of carbolic acid, we have a preparation that meets the requirements, and hence becomes at once a valuable addition to our local therapeutics. In compounding this preparation we must insist that the drugs be chemically pure; otherwise the crude elements of the carbolic acid, or the impurities present, will be markedly irritating. It has been my custom to employ this combination in its full strength.

The use of this preparation, when applied locally for the alleviation or cure of furunculosis of the external auditory meatus, is founded upon its inhibitory action on the development of the staphylococcus pyogenes aureus, and incidentally on its marked anesthetic properties. Granting this hypothesis to be correct, it is only proper to expect that this solution of camphor and carbolic acid will not only shorten the disease in question if seen early, but should also lessen the suffering and limit the course of a case well advanced.

From a practical knowledge obtained by an experience of more than eight years in the employment of this preparation I feel justified in offering the claims stated as reasonably correct. Many cases of incipient furunculosis can be successfully aborted by introducing a cotton tampon saturated with carbolized camphor into the meatus. Even when the furuncle has so far advanced that an incision becomes necessary, the pain incident thereto can be greatly lessened by previously introducing a similar tampon, a few minutes only being required for more or less complete anesthesia to take place. Likewise, after the boil has been opened, the pain will be almost immediately relieved by the introduction of a piece of cotton-wool saturated with this solution. In the latter case, however, the tampon should be large enough to fill the circumference of the meatus, and extend well beyond the boil, as the pressure exerted by the cotton assists in promoting rapid absorption, and thereby facilitates quick recovery. Before each tampon is introduced, the canal should be carefully mopped out with alcohol, as this is our most efficient means of clearing the meatus of all débris, and the alcohol, moreover, is an excellent antiseptic. It may be necessary to apply a fresh tampon of camphor-phenol every day until five or six have been introduced, but two or three are usually quite sufficient to destroy all disease-germs. An ointment of yellow mercurous oxid (gr. ½ to ʒj) can be substituted for the camphorated phenol as soon as the inflammation begins to show marked signs of subsiding.

In advocating this line of treatment it should not be understood that by so doing we would exclude other therapeutic measures of more or less value. In selected cases blood-letting or blistering in front of the tragus is of undoubted service, and hot antiseptic irrigation of the meatus should be employed when indicated. I should like also to mention the value of dry cold in the treatment of inflammatory conditions of the external and middle ear. This, however, will be treated of more at length in a future communication. The use of poultices is mentioned here only for the purpose of discouraging their use. The single benefit that could arise from the employment of hot poultices is the questionable good that may result by promoting suppuration. In so doing, however, one creates a populous hot-bed for the rapid multiplication of bacteria, and frequently excites an inflammation of the auricle. Moreover, the few cases of middle-ear disease that I have seen occur as an extension from the inflamed meatus have invariably resulted after frequent poulticing had been practised.

In debilitated subjects the general health should receive due consideration. The administration of selected tonics, and those drugs known as alteratives, in conjunction with proper hygienic surroundings, will do much to effect the cure of an existing boil, and especially to prevent its recurrence. For this purpose I would strongly urge the use of arsenic in the form of Fowler's solution, given in increasing doses until the physiologic effects are produced. The administration of calcium sulphid, although popular for a time, has on the whole been disappointing in my experience.

In conclusion, I may state my belief that aural furuncle is both infectious and contagious, with a tendency to recurrence from auto-inoculation, and that it occasionally manifests itself epidemically. I can only add that I do not recall a single instance in which there was a recurrence of the furuncle in any portion of the canal, providing strict antisepsis was maintained, and all these important therapeutic measures were applied to the case.

To summarize briefly the treatment of furunculosis of the external auditory canal:

1. As antiphlogistic measures, use the leech or blister in front of the tragus, and hot antiseptic irrigation, when indicated. Avoid the use of poultices.

2. As local applications, cleanse the canal with alcohol and insert an ample tampon of cotton-wool saturated with camphor-phenol, renewing this every twenty-four hours, or oftener if required. This is at once antiseptic and analgesic.

3. As constitutional remedies, give tonics and alteratives, with the especial recommendation of arsenic in the form of Fowler's solution. This should be administered in increasing doses until its physiologic action is obtained.

4. As an operative procedure, make a free incision through the boil, and divide the periosteum down to the bone. This will prove necessary in well-advanced and chronic cases, especially when pus has already formed.

1502 WALNUT STREET.

CLINICAL MEMORANDA.

SIX CASES OF DIPHTHERIA TREATED WITH THE ANTITOXIN.

BY EDWARD P. BREWER, M.D., PH.D.
OF NORWICH, CONN.

CASE I.—The patient was a girl, seven years of age. Her brother had just died of diphtheria after an illness of three days. She was stricken suddenly and violently. Twelve hours from the onset the pulse was 120, respiration 30, and the temperature 103.3°. The tonsils were partly covered with a thick, yellow membrane; there was a patch on the pharynx, and the nostrils were so invaded that nasal respiration was impossible. The voice was hoarse and husky; a short, croupy cough occurred at short intervals. The glands in the neck were swollen and tender. Under these conditions two cubic centimeters of Aronson's diphtheria-antitoxin were injected. Twelve hours later, the temperature became normal, the respiration 18, and the cough less frequent and softer in tone. The pulse-rate continued 120 per minute. Thirty-six hours after the injection the nasal membrane was exfoliating in great masses; the tonsils were nearly clean, and the pharyngeal membrane had disappeared. The voice was less hoarse, and the cough practically subdued. At the expiration of five days every vestige of the disease had disappeared. The pulse continued rapid for several days. No other medicine was used, not even a gargle.

CASE II.—A boy, aged two years, a brother of Case I, was exposed to the disease, and was inoculated with one-half cubic centimeter of Aronson's antitoxin. The following night the boy developed membrane upon both tonsils. The thermometer registered 102°, and the pulse and respiration were proportionately increased. One-and-one-half cubic centimeters of Aronson's antitoxin were now given. In twelve hours the temperature and respiration became normal. In twenty-four hours the membrane began to exfoliate. On the third day the tonsils were clean. The pulse-rate was gradually reduced, and returned to normal on the fifth day.

CASE III.—A brother of the cases cited, aged four years, was injected with one cubic centimeter of Aronson's antitoxin. Six days later he developed diphtheria. The tonsils were well covered with a thick and yellow-colored membrane which resembled chamois-skin. The temperature was 101.5°, respiration 24, pulse 120. Having exhausted my supply of antitoxin, mercuric chlorid was given in doses of one-hundredth of a grain every two hours. The following day the temperature was 102.5°, respiration 24, pulse 125. The membrane had extended to the pharynx. The lymphatic glands in the neck became greatly infiltrated. During the next twenty-four hours the condition became more grave, the lymphatic swelling increased, the thermometer registered 103.5°, the respiration 32, and the pulse 140. The tonsils and pharynx were entirely covered with membrane and the uvula and soft palate were involved. At this juncture, I obtained a supply of Roux's antitoxin, made by the Pasteur Institute of New York. Twenty-five c.c. were injected into the back of the patient. The bichlorid was continued. Twelve hours later the temperature was 101°, respiration 25, pulse 140. Twenty-five c.c. of the Roux antitoxin were again injected. After an interval of ten hours I again visited the patient. The temperature was now 100°, respiration 20, pulse 130. Forty-eight hours after the first injection the quantity of membrane was perceptibly diminished. The progress of the case was satisfactory, but much slower than that of the others, five days elapsing before the throat was free from membrane. The bichlorid was continued until the membrane disappeared; then a chalybeate tonic was ordered.

CASE IV.—I was called on December 11th to see a lady aged about thirty, suffering from a sore-throat. The tonsils were partly covered with a light-gray membrane, the glands of the neck were somewhat enlarged and tender, and the temperature was 101°. The head ached violently, the neck was stiff, and the prostration was sufficiently intense to confine the patient to bed. While the case bore the general characteristics of diphtheria, I deemed it best to defer the use of the antitoxin until the diagnosis should be more certain. I therefore ordered five grains of sodium sulphite every two hours, and that the tonsils be brushed every two hours with a compound of carbolic acid, five parts, Monsel's styptic, thirty parts, glycerin, sixty-five parts. On December 12th the quantity of membrane was increased, and the glandular swelling in the neck greater. I now injected fifteen c.c. of Roux's antitoxin and discontinued the other medicine. On December 13th the membrane on the left tonsil had diminished, but it had increased on the right. Ten c.c. of Roux's antitoxin were injected. A gargle of one part of Labarraque's solution to twenty of water was used hourly. On December 14th the membrane had disappeared from the left tonsil and was reduced in amount on the right. On December 15th the membrane had disappeared from the throat. The gargle was continued for three days. A simple tonic was then ordered.

CASE V.—A young lady of twenty years developed a slight soreness of the throat, accompanied by chills, fever, and infiltration of the lymphatic glands of the neck. On the following day a light-yellow membrane appeared on the left tonsil. By night the left tonsil was nearly covered, and the right tonsil and pharynx showing a small patch of membrane. The temperature was 102°, pulse 110, respiration 22. Twenty-five c.c. of Roux's antitoxin were injected into the lumbar region. A weak boric-acid gargle was ordered. The next morning the temperature and respiration were normal, the pulse numbering 100. In forty-eight hours the membrane was mostly exfoliated. In seventy-two hours from the time of injection the membrane had entirely disappeared. Recovery was rapid and complete.

CASE VI.—A child, four years of age, had been ailing for several days, but was able to be about. The mother noticed swollen glands in the neck and some membrane in the throat. I was now called, and found the temperature 101°, the pulse 130, respiration 19. Both tonsils showed a patch of membrane about one-half inch in diameter. I advised the use of the antitoxin, but the parents objected. So the mercuric chlorid was given in doses of $\frac{1}{100}$ grain every three hours. This treatment, with various local applications, was continued for seven days. The membrane decreased, but did not disappear. On the seventh day of this treatment the child had a chill, the membrane increased, and the voice became hoarse. The temperature was 102°, pulse 140, respiration 24. I now insisted upon the use of antitoxin. Assent being given, I injected 25 c.c. of the Roux antitoxin, and discontinued all other medicines. The temperature rapidly returned to the normal; the pulse and respiration being but little affected. In twenty-four hours the membrane was reduced in amount, but did not disappear until the fourth day following the injection.

REMARKS.—A common hypodermic syringe was used. Great care was exercised in sterilizing it, particular attention being given to the packing on the piston. The skin at the point of injection was washed with a 5 per cent. solution of carbolic acid. The bottle containing the antitoxin, and also the hands of the operator, were sterilized. When the Roux preparation was used the syringe was filled, the needle inserted and the barrel emptied. The barrel was then carefully detached, leaving the needle *in situ*. The barrel was then refilled and emptied until the required amount was injected. In using the Roux serum a syringe of large capacity is needed, for although the plan described is not especially painful, it is a somewhat awkward process with young and frightened children. Massage was not used to diffuse the antitoxin, and, excepting a slight edema, no local reaction was observed. The place of injection is unimportant. Probably the back is preferable, because it is the least painful.

The quantity of serum injected must vary with the preparation employed. The Aronson serum, which has been largely used in England, is the strongest and most easily used. The first injection is generally 5 c.c., and followed by from ½ to 1 c.c. twice daily, as the case shall demand. The Behring serum is supplied in three strengths—No. 1, containing 600 antitoxin-normals; No. 2, containing 1000 antitoxin-normals; and No. 3, containing 1500 antitoxin, normals. According to Behring and Ehrlich, an antitoxin-normal possesses the power of neutralizing ten times its quantity of diphtheric toxin. Serum No. 1 is used only in children under ten years of age, and the whole quantity is given at a dose, and repeated on the following day. Serum No. 3 is two-and-one-half times stronger, and should be employed in patients over ten years of age. Each package contains a single dose.

The Roux serum seems destined to become the popular preparation. It is dispensed in bottles containing 25 c.c.

According to M. Lesage, the following are the best rules for the use of antitoxin: Twenty-five c.c. should be injected as soon as the diagnosis is established. Twenty-four hours after the injection the fever diminishes or disappears, the pulse returns to normal, the general condition improves, and the albuminuria decreases or disappears. One injection may suffice for a cure. If, however, after a period of amelioration the symptoms of infection reappear, a second injection of 25 c.c. must be given at once. If, after twenty-four hours, the condition is stationary, a second injection must be employed. If, after a second period of twenty-four hours, there is still no amelioration, a third injection of 25 c.c. should be given. If the three injections avail nothing, the prognosis is grave, and a fatal issue may be feared.

The dose required for immunization is not definitely determined. While Katz and others have reported a large number of instances in which preventive inoculation was practised, with failure in only 10 per cent. of the cases, it is not proved that these children were really infected. Prof. Bokai believes that the disease may be only held in abeyance, and develops after five or ten weeks. In Case III diphtheria became manifest six days after an immunizing dose of Aronson's serum, and in Case II on the following day. In suspected cases of diphtheria, when there has been exposure to infection, from 5 to 10 c.c. of the Roux antitoxin may be given, and repeated in seven or eight days.

The pulse was not noticeably affected by the antitoxin. In no instance was its frequency reduced, as might have been expected from the mere fall in temperature. The volume in every case was reduced, but this may have resulted from the defervescence.

Carbolic acid and mercuric chlorid are thought to inhibit the action of the antitoxin. Cases III and VI appear to sustain this assertion. Both were given substantial quantities of the sublimate, and were the most tardy in manifesting the good result. While the temperature was promptly reduced, and the general condition improved, the membrane was slowly desquamated, and betrayed a tendency to reappear in small patches in new positions. In Case IV and Case V a gargle of Labarraque's solution (1 : 30) was used hourly during the waking hours. The result was not seemingly affected by it.

No bacteriologic examination was made, nor is it possible in a large percentage of the cases encountered by the general physician outside of the limits of populous cities. While diphtheric membrane may arise from the action of micrococci, staphylococci, and streptococci, and may emphasize the activity and virulence of the Loeffler bacillus, it has been fairly established that the diphtheria-antitoxin is innocuous to all but the Loeffler bacillus, and antidotal alone to its toxin; therefore if the membrane and the systemic disturbance are due to the diphtheria-bacillus, the reaction after the use of the antitoxin is so pronounced in the early stage that there is practically no doubt of the nature of the case, while with the fully-developed case there can be little doubt, and surely no time to be wasted in bacteriologic examination. Scientific accuracy is most satisfactory and interesting, but when weighed against the welfare of the patient it is secondary to the practical test.

INTESTINAL ANASTOMOSIS SUCCESSFULLY PERFORMED AFTER THE LOSS OF THIRTY INCHES OF BOWEL.

By JACOB R. JOHNS, M.D.,
OF DENVER, PA.

THE limitation of the work of the general physician' what should be undertaken and what left to the specialist, is a subject of vital importance. In a special sense is this true with the rural physician, remote from any considerable center of population. To him conditions arise in the night manifestly demanding the immediate attention of both physician and surgeon. Generally neither the patient nor his family is competent to appreciate either the gravity or the indications of the case. Probably an early and strictly aseptic operation alone promises favorable results, while both are practically impossible.

The physician may be strongly tempted to play that comely rôle of the fool, to "rush in where angels fear to tread." If he be a novice, he may be puzzled with the great question of Hamlet, "To be or not to be"—whether to be himself the surgeon or step aside to make place for another.

The case herein detailed was surrounded by many perplexing questions requiring speedy solution.

J. S., of Reamstown, Pa., forty-one years of age, height six feet, weight 150 pounds, a plasterer by trade, of sound constitution and muscular physique, was seized June 15, 1894, with cholera morbus of a severe type in the early morning. He had right-sided scrotal hernia, for which a well-fitting truss had been worn for eight years. On the morning in question, in the agony that followed vomiting and purging, he left his bed, failing to reapply the truss. The bowel descended and became strangulated. Dr. U. B. Kline, senior physician of the place and a man of nearly forty years' experience, was called in consultation. Antispasmodic and relaxing agents were employed internally and externally without results. We decided to operate.

With great difficulty the patient was etherized, yet not perfectly at any time. However, the hernial sac was laid bare and the constriction divided. Upon this the gas escaped and the tumor became much smaller, but the intestine obstinately refused to be replaced. The condition was diagnosticated as twisting of the bowel within the sac, rendering the hernia irreducible.

A surgeon was dispatched for in the person of Dr. Daniel B. D. Beaver, of Reading, Pa., fifteen miles away. Night intervened, during which gas refilled the hernia, and marked swelling resulted. Upon opening the sac eighteen hours later, June 16th, when the surgeon had arrived, an ounce or more of dark fetid liquid flowed out and about two feet of small intestine, black and lifeless, came into view. With this unclean condition of the sac and its contents it seemed best to postpone the reparative operation, and for the time establish a fecal fistula. Accordingly the inguinal ring was further enlarged and the intestines sutured to the abdominal walls.

An effort was made to restore the circulation; but the die was cast: the bowel was dead. Constriction by torsion, augmented by pressure of gas from within, caused complete obstruction of the blood and feces, and yielded dire results in an incredibly short space of time.

While the lines of demarcation were forming, the dressing consisted of cloths wrung out of hot solutions of corrosive sublimate, 1 : 4000, retained by a flannel diaper. This was renewed from every two to four hours. On the second day the bowel was punctured to liberate the fluid and gas. On the third day the bowel was stripped, and in the second week two feet of dead bowel were excised.

The condition of the patient during the first week was most critical. For five days the ingesta consisted almost entirely of cold water. Constant nausea and hiccough persisted for several days. The temperature, however, never rose above 100.4°, and after the fifth day was constantly normal.

For the psychic effect and to irrigate the colon, three rectal injections were given. But the small intestine was most profoundly inactive. The cholera morbus, as also the graver circumstances that followed, had left its morbid imprint here. On the fourth day, when vigorous treatment was imperative, the foot of the bed was again lowered and calomel and sodium bicarbonate, āā gr. ss, were administered every hour till decided effects were produced. Thus fecal movement by the artificial anus became established, nausea and hiccough disappeared, and appetite returned.

Near the close of the second week there was constant escape of feces, acid in reaction, and containing much undigested food. To control this, fluids were restricted and four grains of opium given daily. The fecal movements then became three in number daily. The dry diet was continued, while the opium was gradually reduced and omitted.

The incision into the scrotum healed by second intention. The danger from secondary infection was reduced to a minimum by keeping the wound constantly covered with iodoform, 1, powdered boric acid, 4. Over this was placed surgeon's cotton charged with carbolized cosmolin. Quilting cotton was largely used to catch the fecal discharges. This was so disposed as to direct the feces toward the left groin. The dressing was renewed twice daily. In the third week, when all dead tissue had been removed, it was found that the line of dermarcation in the distal end had formed beyond the retaining stitches, thus allowing the end to escape into the abdomen. The alarm occasioned by this was but transient. The inguinal ring immediately over this retracted end showed no disposition to close. The secretions—mucus, slough, pus, etc.—appeared on the outside, even in the fourth week.

Convalescence was rapid in the fourth week. The patient sat in a chair an hour daily and freely discussed the operation for resection.

On July 13th Dr. Beaver, accompanied by an assistant, Dr. Daniel Longaker, again came upon the scene. At this time, as has been noted, the distal end of the bowel had been retracted out of sight and beyond reach. The proximal end had become invaginated and protruded in treble thickness, mucous surface external, three inches, in spite of the pressure that had been on the fistula since the primary operation.

The operation for intestinal resection was strictly aseptic, and demonstrative of the fact that this is possible even in the humblest rural home. On the preceding day the patient's bed-room was rendered as clean and sweet as any hospital ward, and the patient thoroughly scrubbed. Perfectly uniform anesthesia was obtained by supplementing ether with chloroform in small quantities, as needed. End-to-end anastomosis was made by means of a Murphy's button seven-eighths of an inch in diameter.

The first step of the operation was to open the abdomen in the linea semilunaris. The incision extended from a point three inches above the external inguinal ring down to the knuckle of gut that protruded from it. The adhesions between this knuckle and the ring were so extensive, and the tissue so vascular, that it was thought better to ligate the bowel internally than to detach it from the outside. Accordingly, a ligature was put around it close to the inner surface of the abdominal wall. Clamps were then put on both ends of the bowel half an inch above the ligature, and the bowel and involved mesentery severed between them and the ligature. Several large mesenteric vessels were now ligated, and the mesentery trimmed back an inch from each end of the bowel. The puckering strings were put into the ends of the bowel, and the button inserted in the manner described by Dr. Murphy. Then, after approximating the cut edges of the mesentery by means of a few fine silk ligatures, the bowel was dropped into the abdomen and covered with a warm, wet sponge. The stump of gut in the inguinal ring was now turned out by tearing the adhesions between it and the abdominal wall. This was followed by rather free bleeding, which ceased, however, while the sutures were being put into the upper part of the wound. The whole incision, including the inguinal ring, was closed by a single set of silkworm-gut sutures. The lower end of the wound, from which the attached gut was torn, healed by second intention, forming a thick, firm cicatrix, and will, as indicated by present appearances, be the last part to give way before pressure of the contents of the abdomen.

Dr. Murphy's button is a very ingenious contrivance, and one that marks a step in the advance of bowel-surgery. The insertion of the button is decidedly the simplest part of the operation for intestinal anastomosis. It may be accomplished with ease and rapidity, and secures perfect approximation of the peritoneal surface of the ends of the bowel, while it avoids completely all communication between the lumen of the bowel and peritoneal cavity—the dangerous feature of all methods in which approximation is secured by means of sutures.

Although the application of this button is simplicity itself, there should be borne in mind certain common physical facts in its use. In cases of fecal fistula involving the small intestines, the distal, unused portion of the bowel always contracts with time. In this case it had contracted to less than three-quarters the caliber of the proximate portion in four weeks. The upper portion of the bowel having been of large size, the largest button, which seemed small for it, was taken, and one section inserted. When the counterpart was applied to the distal end it could be inserted only with much difficulty, and with dilatation of the gut. In fact, it stretched the gut so, that in a few minutes it became pale from obstruction of the blood-circulation. This appearance of the bowel led to fear of impaction of the button and sloughing of the tissues around it. It was, therefore, extracted and the next smaller size inserted with ease. With this the bowel maintained its normal color. It is probable that this was as large a size as could be used with safety, and it is also quite likely that, as it remained with the patient seventeen days, it had to dilate the bowel on its way down. In such cases the proper plan is undoubtedly to put the button into the distal end first, and use the largest size this will admit without undue stretching and interference with the capillary circulation.

Excepting a little nausea, a slight pain felt in the right inguinal region only on deep inspiration the first and second day, a feeling of fulness the first night, and less than two degrees of surgical fever, there were no discomforts. Gas passed downward at once.

A stool of bloody secretions mixed with feces was had twelve hours after the operation. After the eighth day there was daily fecal movement: at first four or five times daily, but gradually less often. On the tenth day the first evidences of detaching slough appeared in the stools. The button, however, did not pass till the seventeenth day, when, for the first time, the chamber was used instead of the bed-pan. The patient was apprised of its appearance only by seeing it in the chamber

Milk in the form of ice-cream, made rich by the addition of eggs, eaten slowly, was the main article of diet the first week.

Though the total loss of intestines was thirty inches from the jejunum, I judge, convalescence was uninterrupted, rapid, and perfect. Two weeks were spent in bed, and two more about the house, making in all, from the attack of cholera morbus, eight weeks.

A supporter for the abdomen was improvised by replacing the pad of the patient's adjustable ratchet-clutch truss, by a concave, kidney-shaped board, 4 x 7 inches. Instructions were given to wear this one year.

The operation has proved a radical cure of the hernia.

To show that the loss of thirty inches of small intestine in an adult is not incompatible with perfect bodily nutrition I append the following:

The gain in flesh after the final operation, and before the patient left the house, was considerable. In the fifth week, when he was weighed, twenty-two pounds of his original weight were still lacking. The first week after weighing, with daily outdoor exercise, he gained six pounds; the second week, four pounds; the third week, three pounds; the fourth week, two pounds; and at the date of writing, the thirteenth week after the first operation, he has reclaimed the last pound, and feels that he is again quite himself in every particular.

A UNIQUE CASE OF INTESTINAL FISTULA FOLLOWING CELIOTOMY.

BY LOUIS FRANK, M.D.,
LOUISVILLE, KY.,
ASSOCIATE PROFESSOR OF OBSTETRICS AND DIRECTOR OF BACTERIOLOGICAL LABORATORY, KENTUCKY SCHOOL OF MEDICINE;
GYNECOLOGIST TO LOUISVILLE CITY HOSPITAL;
OBSTETRICIAN TO KENTUCKY SCHOOL
OF MEDICINE HOSPITAL, ETC.

A. T., twenty-eight years of age, a widow, was referred to me in June last by Dr. Shrum, of Bedford, Ind. She gave a history of dysmenorrhea of most decided character, dating back five years, at which time she had had a child, the only one she has ever had, and the birth of which was followed by puerperal fever. At each menstrual period she was confined to bed for quite a number of days, both before and after the flow. She had been absolutely incapacitated for work of any kind, and had been bedridden a greater part of the time.

Digital examination revealed exquisite tenderness on both sides, and the presence of a great deal of infiltration in both broad ligaments, with what was taken to be double pyosalpinx. An operation was, of course, advised, and carried out on June 23, 1894. Very dense adhesions were found upon both sides, those on the right being the denser, this tube being imbedded in a perfect mass of adhesions composed of the intestines, uterus, bladder, etc. After some very difficult work the tube was finally enucleated, as was also the left tube, this, however, more easily than the right. A drainage-tube was introduced, and the abdomen closed and dressed in the usual manner. Through the tube a strip of gauze was carried back and inward on the right side, upon which side the adhesions had been so dense and numerous; on this side on account of the great amount of infiltration and the thickening of the ligament—it being fully three-quarters of an inch in thickness—very heavy ligatures were applied to the broad ligament. The gauze was removed after twenty-four hours, and, although there was not much fluid upon aspiration, the tube was left in longer for fear of hemorrhage, being removed on the morning of the third day.

The patient did unusually well, without any elevation of temperature, the bowels moving in due time, until the sixth day, at which time the patient developed some tenderness along the point of the incision; the dressings were removed, but nothing unusual found. At the end of a couple of days more she was still complaining, and the dressings were again removed and the stitches taken out. Provisional sutures had been put in at the point of drainage, and when these were removed there was a gush of slightly sanguineous fluid, very thin in consistency, with, however, no indication of pus. This left a fistulous tract. The fistula was treated with hydrogen dioxid and packing, and closed in a couple of weeks. The woman had also a great deal of vesical tenesmus, followed by a violent cystitis, which kept her in bed for a week longer. The temperature in the meantime had subsided to normal, and there was absolutely no indication of there being anything amiss. About the sixth week she became obstinately constipated, resisting salines, calomel, and enemata of water and of water and glycerin, etc. This constipation continued for five days. The woman was then again put upon two-dram doses of Rochelle salts, repeated every hour, and these were continued until she had taken about four ounces. All at once there occurred one morning a gush of fluid mixed with a little fecal matter from what had previouly been the sinus. A short while afterward the bowels moved, the action being very copious and repeated a number of times. Examination then showed that a fecal fistula had established itself at the point of drainage. This fistula was treated by local applications, tonics were ordered, and the bowels were kept open. In about ten days the fistula had closed absolutely, there never having been, however, any escape of fecal matter since the first discharge mentioned, but the patient had continued at times to pass a little gas through the opening.

The woman was now sent back home, directions being given her physician to watch her from time to time. Later it was learned by letter that the fistula had again reopened, and that gas was occasionally passing, and also that she passed several lumbricoides through the fistulous tract. The fistula remaining open, she was again sent to me for operation, but my clinic not being in session she was referred by me to the clinic at the Louisville Medical College, where she came under the care of Dr. A. M. Cartledge, who dissected out the fistulous tract, and closed the opening in the bowel in a most beautiful manner, the patient making a perfect recovery.

A letter which I have recently received from Dr. Shrum (and another from Dr. Stipp, who had the patient under observation after I sent her home) states that she has never passed any fecal matter through the fistula since coming under his observation. The patient herself says that she has passed in all seven lumbricoides through the fistula; that upon two occasions others have come to the external opening, partly protruding so that she has been able to see them, and then go back. She has had absolutely no pain except just previous to passing a lumbricoid, when she would have a great deal of pain, and she says that she always knew when one was coming.

The operation revealed, as had been suspected, that the fistulous tract was in the track of the drainage, and that at the bottom there was the ligature that had been applied to the broad ligament, and had no doubt become infected through the drainage-tube. At this point a knuckle of gut was adherent, forming almost a complete loop, the fistula itself being drawn up by the intestines and seeming bent upon itself.

I report this case on account, first, of the fact that seven weeks elapsed from the time of the first operation until the establishment of the fecal fistula, which, however, is possible, as Senn has shown us, when the cause of these fistulæ is an infected ligature. Another reason is the passage of the lumbricoides, which, in itself, is a very unique feature, and something that I have not seen mentioned in literature, though I have searched for it very diligently.

419 West Chestnut Street.

MEDICAL PROGRESS.

A Tumor of the Lumbar Region of the Spinal Cord.—At a recent meeting of the New York Neurological Society Van Gieson and Fisher reported the case of a carpenter, sixty-one years old, with a negative family history, but a personal history of syphilis at the age of twenty-five, who for about six months before coming under observation suffered from pronounced dizziness on standing erect. His memory was good. There was diplopia of three years' duration. Hearing was good; speech was normal; there were no gastric symptoms. For eight months there had been retention of urine and frequent and severe attacks of diarrhea. There was an entire loss of sexual desire. There was no weakness or ataxia of the upper extremities, but progressive loss of power in the lower extremities, of about one year's standing. There had never been any twitching or convulsions, and no hyperesthesia. There was a feeling of numbness from the waist down. The mental condition was unimpaired. The pupils reacted both to light and in accommodation; the visual fields were normal. There was no paralysis of any of the cranial nerves. Coördination in the lower extremities was impaired, the patient being unable to stand erect, and falling to the floor unless supported. The condition of the muscles was unchanged. The gait was markedly ataxic, and the patient was unable to walk at all without assistance. There was a gradual loss of sensation to touch and pain in both feet, more pronounced on the right side. The knee-jerk on the right side was entirely abolished; on the left side it was normal. Finally, a large bed-sore developed over the sacrum, and death soon followed.

The post-mortem examination disclosed an extramedullary tumor of the spinal cord, cylindrical in appearance, and measuring a little more than an inch at its broadest part, and extending from a little above the second lumbar segment downward into the cauda equina a distance of nearly three inches. It rested on the ventral surface of the cord and at about the level of the fourth lumbar segment. By pressure it had begun to produce some distortion of the cord. At the fifth lumbar segment this distortion was very striking, both the anterior and posterior horns being compressed into a thin mass. In the sacral region the pressure-effects were less marked. The extreme tip of the cord was found to be curled upward on itself as far as the fifth sacral segment. Whether this retroflexion was caused by the growth, which perhaps enlarged from below upward, could not be determined. The neoplasm proved to be a glio-sarcoma.

The Amounts of Calcium, Magnesium, and Phosphoric Acid in the Urine and Feces in Osteomalacia.—As the outcome of a quantitative investigation, Neumann (*Archiv für Gynäkologie*, Band xlvii, Heft 2, p. 220) has arrived at the following conclusions:

The secretion of lime by the kidneys in the progressive stage of osteomalacia scarcely differs from the normal. In the stage of regeneration of bone, as compared with the progressive stage, and thus as compared with the normal, smaller amounts of lime are excreted with the urine, so that a greater retention than occurs in the first stage would be assumed if one were to judge from the constitution of the urine alone. If, however, the total amount excreted both in the urine and in the feces is made the basis of calculation, it appears that the retention is really less in the second stage than in the first. During the progressive stage the organism suffers a small loss in magnesium. In the stage of bone-regeneration, however, small amounts of magnesium are retained. In osteomalacia the normal relation of 1 : 3 of lime to magnesium is changed in favor of the former. In the first stage there is a pronounced excretion of phosphoric acid, so that the entire organism, and more particularly the bones, suffers the loss of large amounts of phosphoric acid. In the regenerative stage of the disease comparatively large amounts of phosphoric acid are retained in the organism; the quantity corresponds approximately with the loss of phosphoric acid during the first stage. Therapeutically these observations confirm the wisdom of administering phosphoric acid in conjunction with improvement of the hygienic and nutritive conditions.

Persistence of the Foramen Ovale in a Boy of Eight Years, with Clubbed Fingers.—Stembo (*St. Petersburger medicinische Wochenschrift*, 1894, No. 41, p. 366) has reported the case of a boy, eight years old, who presented no special peculiarity until he reached the age of five-and-a-half years. At the age of three he had a severe attack of scarlatina, complicated by nephritis. At this time slight cyanosis was observed. Shortly afterward, following emotional disturbance, the child became short of breath and markedly cyanotic. Subsequently, he had an attack of typhoid fever, then one of pneumonia, and some time later one of smallpox. He came under observation on account of an attack of parotiditis. Attacks of bronchitis recurred, and frequently from time to time hemoptysis, and the stools also contained blood. The child was defective in development, and presented marked cyanosis. The veins of the neck pulsated, the chest heaved between the second and fourth costal cartilages on the left, and pulsation was apparent in the epigastrium. The abdomen was notably distended. The tips of the fingers were markedly enlarged. Upon palpation marked pulsation was evident at the lower portion of the sternum, and also in the situation of the pulmonary artery. The area of cardiac percussion-dulness was increased, and formed a small square between the second and fourth ribs on the left side next to the sternum. On auscultation a systolic murmur was heard at the apex, and also over the sternum in the pulmonary area. The second sound was accentuated. The systolic pulmonary murmur was heard over the left carotid, though more faintly. The case was believed to be one of persistence of the foramen ovale.

Traumatic Hemothorax in the Newborn.—Gebhard (*Zeitschrift für Geburtshülfe und Gynäkologie*, Band 30, Heft 2, p. 402) has reported the case of an infant born with some difficulty by the pelvis with artificial aid. The resulting asphyxia was overcome by the institution of artificial respiration, but death took place three hours after birth. Upon the removal of the sternum a teaspoonful of liquid and dark-colored blood escaped from the right pleural cavity and two teaspoonfuls were additionally removed. Beneath the epicardium and near the coronary sulcus and the apex of the heart were several small extravasations of blood. Beneath the pulmonary pleura at the base of the left lung there was a more extensive extravasation, while over the upper lobe were several smaller ones. Upon removal of the thoracic viscera the pleura of the posterior wall of the right half of the chest was observed to be elevated by an effusion of blood extending along the vertebral column from the first to the sixth rib. Over the head of the second rib was a tiny wound of the pleura through which blood escaped. After careful removal of the pleura it was found that the second intercostal vein was ruptured at a point a few millimeters before its entrance into the azygos vein. There was no interruption in the continuity of the ribs or of the costo-vertebral articulations, although there was undue mobility of the head of the second rib in its articular capsule. The injury to the vein, with subsequent hemorrhage into the pleural cavity, was ascribed to the manipulations necessary to establish respiration, with the result of causing such compression of the lung as to lead to death.

THERAPEUTIC NOTES.

The Treatment of Diphtheria with the Antitoxin.—At a recent meeting of the Royal Society of Physicians of Vienna, WIDERHOFER (*Wiener medicinische Presse*, 1894, No. 52, p. 2013) reported the results obtained in 100 severe cases of diphtheria treated during October and November with the antitoxin. Of this number, 74 recovered, 24 died, and 2 were yet under observation. Bacteriologic examination was made in all instances but 2; diphtheria-bacilli were found in 96. For the preceding nine months the mortality had been 52.6 per cent.; for the corresponding two months of 1893, 44 per cent., of 1892, 39 per cent., and of 1891, 34.2 per cent. From 1862 the mortality has fluctuated between 32.3 per cent. and 71.9 per cent.

At a recent meeting of the Clinical Society of London, MACCOMBIE (*British Medical Journal*, No. 1774, p. 1484) related that of 31 cases of diphtheria treated with the antitoxin, 3 had died and 1 more was probably going to die. During the period of treatment a total of 54 cases came under observation; but to some, partly on account of the lateness of the period, and to others, partly on account of their age, the antitoxin was not administered. Among the whole number there were 7 deaths. In January, 1894, the mortality among 21 cases of diphtheria had been 42 per cent.; during February, among 17 cases 35 per cent.; during March, among 16 cases 31 per cent.; during April, among 24 cases 29 per cent.; during May, among 23 cases 30 per cent.; in June, among 32 cases 34 per cent.; in July, among 70 cases 37 per cent.; in August, among 43 cases 18 per cent.; in September, among 57 cases 29 per cent.; in October, among 48 cases 25 per cent.; in November, among 23 cases 25 per cent.

CAIGER (*Ibidem*) related that he had treated 30 cases of diphtheria with the antitoxin, with 8 deaths. Of these, 5 died within 12 hours of coming under observation, and 3 of the 5 within 3 hours. The mortality had previously been 30 per cent. for two months consecutively.

The Use of Sulphur in Surgery.—At a recent meeting of the Royal Medical and Chirurgical Society, LANE (*British Medical Journal*, No. 1770, p. 1239) reported the results of a year's experience with the use of sulphur in surgical practice. He found that neither sulphur nor the products generated by its decomposition acted prejudicially upon the life or health of the individual into whose body it was introduced. If placed in contact with recently-incised healthy tissues, twenty-four hours sufficed to render the parts sterile as far as organisms are concerned. If the recently incised or scraped surfaces be but poorly supplied with blood, as, for example, the brawny edge of a carbuncle, or the spreading gangrene of a limb, sulphur may be left in contact with the tissues advantageously for a considerably longer period. This also applies to granulating surfaces. The entry of other organisms into a tuberculous cavity does not influence the action of the drug, as it destroys all organisms, whether free in the cavity or intruding into the surrounding living tissues forming its wall. The action exerted by sulphur is a painless one.

Amblyopia Due to Di-nitrobenzol.—POCKLEY (*Australasian Medical Gazette*, vol. xiii, No. 10, p. 340) has reported the case of a "mixer" in a roburite factory, thirty-one years old, who complained of failure of sight. There had also been breathlessness, aggravated by exertion, blueness of the face, hands, and feet, and vertigo. There was ability only to count fingers at a distance of three yards. There was no central scotoma for red or green, and there appeared to be slight concentric contraction of both fields. The pupils were slightly enlarged and sluggish. The discs were uniformly pale and flat. Under treatment with strychnin, vision slowly but steadily improved. It appears that di-nitrobenzol is employed in the preparation of roburite, an explosive, and that breathlessness and blueness of the face are common among mixers that are careless as to the state of their hands. The symptoms may also appear as a result of inhalation of the fumes.

Pilocarpin for Urticaria.—ABRAHAMS (*Medical Record*, No. 1245, p. 342) recommends the employment of pilocarpin hydrochlorate in the treatment of acute and chronic urticaria, and reports three illustrative cases. To adults he gives from gr. one-sixth to gr. one-half daily or every second day, or even oftener, injected subcutaneously. To children the drug is administered by the mouth, to a child a year old, in doses of from gr. one-twentieth to gr. one-eighth, at bedtime; to a child from two to three years old in doses of from gr. one-fifteenth to gr. one-sixth.

MCBRAYER (*Medical Record*, No. 1252, p. 564) has reported a case of urticaria in a boy two years and nine months old, in which relief was afforded by the subcutaneous injections of gr. one-sixteenth of pilocarpin hydrochlorate.

SATURDAY, JANUARY 19, 1895.

THE RELATION OF THE BACTERIOLOGIC DIAGNOSIS AND NEW TREATMENT OF DIPHTHERIA TO LABORATORY-INSTRUCTION.

To one who is in touch with the present tendencies in medical diagnosis and medical treatment many things are significant. These tendencies can be illustrated in no better way than by the recent work in the diagnosis and treatment of diphtheria, and, since the subject is so fresh and so universally interesting, we shall employ it for our text.

The very essence of the antitoxin-treatment of diphtheria is expressed by the word *specific*. The remedy is a specific for the disease consequent upon the invasion of a certain pathogenic microörganism—the Klebs-Loeffler bacillus. The blood-serum of a diphtheria-immune animal can neutralize only the toxins of the diphtheria-bacillus. It cannot, apparently, neutralize the poisonous products of any other pathogenic microbe. The identification of the organism exciting the disease, then, lies at the beginning of this new therapy of diphtheria. This is accomplished by the bacteriologic diphtheria-test. Furthermore, the remedy appears to be efficient as it is applied early in the disease; so that, not only is a bacteriologic diagnosis demanded in every case preceding the employment of the antitoxin, but an *early* diagnosis must be made.

The value of the diphtheria culture-test has been emphasized in other directions, especially by the work of the Health Department of New York City on the sanitary aspects of a positive diagnosis of membranous throat-diseases. This department has taken the initiative in a commendable effort to bring into its municipal laboratory all the work of diphtheria-diagnosis. We are justly proud of the results already accomplished by this body of energetic investigators, and it seems only natural that the example of New York, in this respect, will be followed in all of our larger American cities.

But the work of such a municipal laboratory, however extensive its operations and however delicate the adjustment of its details, can only hope to be most efficient in those matters of sanitary management hinging on the diagnosis of membranous throat-diseases. It cannot take from the work of the individual physician the tasks that legitimately fall to him—and we maintain that, like many another diagnostic procedure, the bacteriologic test for diphtheria as a prelude to the antitoxin-treatment is one of these tasks. This is so for several reasons. In the first place, it will naturally be a long time before this practice will become general, even among our large cities, for obvious reasons. Even when the work is universally operative in the larger cities, how shall the smaller towns and rural settlements of our vast country be reached? Then there is that ever-present obstacle, *political corruption* in our American cities. Even now, how many of the health-departments of our cities are beyond the influence of the miserable political rings that wield the power of government? Finally, under ideal conditions, the time consumed in a municipal diphtheria-diagnosis severely handicaps it for the requirements of the new treatment.

Looking at the question in all its aspects, there seems but one conclusion, viz., that the work of diphtheria-diagnosis ought to be pursued by each individual physician whose practice brings him into contact with cases of this character. Why should this not be so? Why should this one particular task be taken from the physician, while he is called upon, from time to time, to assume other, and no less difficult, procedures in clinical diagnosis? The culture-test for diphtheria is neither difficult nor complicated. Still, for its prosecution, a fundamental knowledge of bacteriology and bacteriologic technique is demanded; this, alas, the majority of physicians lack. The more energetic and enthusiastic of the younger physicians will acquire the knowledge necessary to enable them to apply, practically, the diphtheria culture-test.

Our great hope, however, lies in the young men now receiving their education in medicine. Are we doing our duties by them? The medical student to-day should be so well trained in laboratory-methods that he could apply, intelligently, not only the diphtheria culture-test, but many other laboratory-tests in diagnosis. This certainly implies a more elaborate and detailed laboratory-training than is now afforded by the majority of our medical schools. It argues, more forcibly than ever before, for that thorough and systematic education of our students that is so well exemplified in the leading biologic schools of our country. Surely, our medical educators will prove themselves equal to these new demands.

SYSTEMATIC INSPECTION OF LIVE-STOCK.

All classes of the community are awakening to the necessity of careful supervision of those domestic animals from which our food-supplies are derived. The relations between tuberculosis and dairy-farming are now so well understood that we need not here discuss them. In many of the United States satisfactory machinery does not exist by which proper inspection may be carried out, and efforts are being made to remedy this defect. Legislation on such questions must be framed with great care; the problems to be solved are novel and involve high technical knowledge; moreover some phases of the question are not fully elucidated by research. A difficulty arises at once in regard to compensation for animals slaughtered. This may be the major expense, and as in most of our States the agricultural classes have considerable political weight no bill is likely to get through a State Legislature unless the owners of animals are satisfied that no material loss will inure to them.

We have before us the text of an act laid before the present Pennsylvania Legislature, which is to create a State Live-stock Sanitary Commission. The first section provides for five commissioners, two to hold by virtue of office, namely the Secretaries of the State Board of Agriculture and of the State Board of Health respectively. The other members, designated by the Governor, are to be respectively a practical breeder and two regular graduates in veterinary medicine. The details of inspection, methods of procedure, and awards of compensation to owners of slaughtered animals are left to the commission. Full power is given to the commission or its agents to enter all places in which animals or carcasses may be kept, and wilful interference with these visitations is punishable.

It is said that this act has been drawn after consultation with all interests affected and under expert medical and veterinary advice. It is not stated whether legal advice has also been taken, though this is very important, as the phraseology of an act becomes often the means of rendering its operation unsatisfactory. We heartily commend the proposition, and hope that prompt legislative action may follow.

The attention which is now being given to this subject is shown strikingly by the recently-issued report of the State Board of Health of New York, in which a special volume of several hundred pages is devoted to the investigations made into the extent to which tuberculosis exists among the herds in that State. In many of these a large proportion of infected animals was found. It is worthy of note that herds of the finest grades are quite as likely (indeed, perhaps more likely) to be infected as inferior strains, and this indicates that the striving after special qualities of milk is liable to intensify the danger from disease.

The agitation of the question of the danger from the use of infected milk has resulted in diminishing the use of milk. Statistics show that in the last three years the amount of milk consumed in Philadelphia has remained stationary, in spite of the increase of population. Some writers on these questions think that unless medical reform is soon accomplished the decrease in the use of milk and milk-products will be so great as to prevent dairy-farming being profitably pursued.

EDITORIAL COMMENTS.

Courses Preparatory to Medicine.—The University of Nebraska is to be warmly commended for a step that it has undertaken in the direction of higher medical education. It is palpably wiser to include certain branches o study in preliminary courses, and thus to some extent lessen the burden of the medical course proper, and keep within reasonable limits the time necessary to be devoted to it. The University of Nebraska has instituted a special course preparatory to medicine, open to students of both sexes, and the requirements for admission to which are a fair mastery of English grammar, arithmetic, descriptive and physical geography, and elementary United States history.

A student presenting satisfactory certificates or passing creditable examinations will be given full credit for any work accomplished before entering the University; and can thus shorten the time to be spent there.

The first year's work includes a thorough course in English, a course in Latin, algebra to quadratics, and the first two books of geometry; the logic-making studies, and elementary courses in botany, chemistry, and physics. In the second year the student carries structural and physiologic botany; in chemistry, the metallic elements and their more common compounds, with five hours' laboratory-practice each week; rhetoric, and constant practice in theme-writing; lectures and laboratory-work in sound and heat, in physics, a strong course in general osteology; and lectures on hygiene and sanitation, with physical training in the gymnasium.

The third year is given to pharmaceutic botany; a continuation of the study of metallic elements, with special study of characteristic reactions—with the usual laboratory-practice; comparative anatomy and human osteology; histology and embryology; a course in psychology, including a study of the nervous system, sense-organs, psycho-physical methods and results, instincts, consciousness, attention, association, habit, memory, emotions, will, dreams, and hypnotism; and a course in general physiology.

Students completing the preparatory medical course receive certificates of their proficiency, and by special arrangement are admitted (without preliminary or entrance examinations) to the third year and second course of lectures of the Cincinnati College of Medicine and Surgery; to the second year in the Boston University School of Medicine, in the Medical School of the University of Pennsylvania, in the Omaha Medical College, and Creighton Medical College, and in the Northwestern Medical School (Chicago Medical College); and to the first year in the St. Louis Medical College, and the Department of Medicine and Surgery, University of Michigan. Other institutions of equal standing have promised similar recognition, but have not yet taken formal action.

The Medical Man and the Trolley-car.—Very soon doctors will have to enter the army or navy in order to escape peril to life and limb. The thoughtless public is delighted with their new conveyance, but the doctor finds it only a deadly peril. It helps him but little if his business is extensive, leaves him to carry by hand his various impedimenta, gives him long walks where the trolley company, *mirable dictu*, has neglected to seize a street, and long waits where it fails to run frequently, and lets him out only at prominent street-corners. He cannot make it wait in grandeur before the doors of his wealthy patients, nor will the motormen and conductors wear his livery. If he drives himself, it wears out his nerves and speedily makes him hysterical or melancholy, with its deadly wire or more deadly dread of collision hanging over the tracks he must cross and recross so often. His neck is sore and stiff from twisting his head to look out of the back window of his carriage, and his eyes take on a divergent squint, which no prism or graduated tenotomy can correct, from his efforts all day to see behind him with one eye while he looks ahead with the other.

At ordinary crossings he must look eight ways at once, and an ingenious scientist has calculated that at complicated crossings, like those in Philadelphia at Ridge Avenue, Spring Garden and Twelfth Streets, or at Twenty-second and Chestnut Streets—and there are many such—he will need to make at least twenty-six single and separate observations before crossing, while if we add to this the additional acts of observation necessary in avoiding foot-passengers at the various crossings and the carts and carriages occupying either side of each trolley track, with those preceding and following the car on each track, with special observations on the nature of the roadway as to holes, uncovered manholes, spots of ice and piles of snow in winter, as to whether the motormen, drivers, and foot-passengers are of imperfect sight or hearing, or imbecile, lame, or disabled from age, we have something like one-hundred-and-two distinct acts of observation needed, and a rapid judgment and decision based upon them, as to whether to go on, back out, or stand still, and this too in a time so short that human limitations as to the rapidity of sensory impressions and consequent motor reaction forbid in many cases the required action in the limited time given.

Yet upon this decision and action the safety and life of the driver will depend, to say nothing of the safety of innocent foot-passengers and others less innocent.

And, still further, the scientist estimates that in the usual morning's work of five hours this rapid observation and decision must be repeated, in more or less complicated conditions, on the average 63.4 times.

Moreover, the trolley-car pursues him after he is safely in his home, and even in his bed—not only with dreams and night-terrors of smash-ups and death, but the sleep-banishing, nerve-shattering gong, ringing always and unnecessarily, scares to death what little nervous and mental stability may be left after the day's wretchedness.

Is it any wonder that doctors are short-lived and that their lives are destined to still greater brevity? Furthermore, our scientist gives us but little hope of any immediate relief, but thinks that in the course of time Nature will, as usual, come to our aid, and bring forth by her handmaid—evolution—from her boundless storehouse new-posterior-occipital eyes, one or more, and that possibly, for here he is on uncertain ground, and fears to excite illusory hope, possibly, the great central cyclopean eye, rudiments of which still survive, may be furbished up in ten or twelve thousand years to meet the emergency temporarily, for the really serviceable new occipital eye, with sufficient backward projection and a swivel-socket like a lobster's, will take from twelve to twenty million years to evolve successfully. Thus does science ever light up the dark places of life with hope.

The Operative Treatment of Ulcer of the Stomach.—It is scarcely possible to assign the limits of modern surgery. Nature has been so prodigal in the dispensation of structure that parts of what have heretofore been considered vital organs may, under suitable conditions, be removed not only without injury, but even with advantage. The number of cases in which celiotomy and suture have been practised for the relief of perforation of a gastric ulcer is growing, and the results are most encouraging. **KÜSTER** (*Archiv für klinische Chirurgie*, Band 48, Heft 4, p. 787) has recently reported a case in which the indications were not quite so urgent, but in which both the symptoms and the results seem to have justified the procedure adopted. The case was that of a girl, twenty-one years old, who three days after lifting a heavy weight was seized with abdominal pain and vomiting. Emaciation occurred, and later convulsions with loss of consciousness. With the vomiting there became associated burning pain upon the right side of the abdomen. The stomach was greatly dilated, the gastric juice feebly acid and without free hydrochloric acid. The right kidney was rather freely movable, and the gastric symptoms were ascribed to the traction of this organ upon the pylorus. For the relief of this condition nephrorrhaphy was undertaken and the displaced organ attached to the quadratus lumborum muscle. Recovery ensued, though complicated by a mild attack of pneumonia. For a time the symptoms were ameliorated, but after more than a half-year the patient returned with abdominal pain and vomiting after the ingestion of food. At a later period copious hematemesis took place and was from time to time repeated. There was considerable loss of weight, and the anemia was pronounced. A diagnosis of ulcer of the stomach close to the pylorus was now made, and for the purpose of controlling the hemorrhage and avoiding secondary contraction the abdomen was opened by an incision parallel with the left costal arch. Upon the posterior wall of the stomach was found an ulcer about as large as a fifty-cent piece, to the surface of which the thermo-cautery was applied. The upper portion of the jejunum was drawn forward and united with the stomach, so that a large communication was established between the two viscera. Recovery was only interrupted by a deep abscess of the abdominal wall, but hemorrhage never recurred after the operation. The patient soon gained in weight and strength, and her former symptoms disappeared.

It is not likely that the conditions will frequently arise under which this method of treating ulcer of the stomach will become necessary, or that its application will be at all general; but both the physician and the surgeon will welcome any reasonable measure that promises to be an addition to their resources in dealing with a condition that is never without danger, and sometimes is most obstinate in its course, and even disastrous in its outcome.

The Relation Between Acute Rheumatism and Endocarditis and Myocarditis.—While it is generally conceded that acute rheumatism belongs in the category of infectious diseases, the proof of a specific mycotic etiology is yet wanting. It is true that several observers have described various organisms both in the synovial effusions and in the lesions of the complicating endocarditis; but the evidence is not sufficient, on the one hand, to ascribe to any one of these specific etiologic properties, or, on the other hand, to justify the conclusion that rheumatism, like pneumonia, may have a multiple etiology, although it is known that articular involvement occurs in connection with gonorrhea, typhoid fever, scarlatina, and smallpox, as well as with rheumatism The etiology of endocarditis is likewise somewhat obscured in doubt, though here the likelihood of multiple etiology is greater than in the case of rheumatism, and is strongly supported by the bacteriologic evidence. While the relation between rheumatism and endocarditis and myocarditis is recognized clinically, the nature of the etiologic relation has not been clearly demonstrated. In an interesting address before the Society for Internal Medicine of Berlin (*Deutsche medicin. Wochenschrift*, 1894, No. 49, p. 913) **LEYDEN** considered this subject, and reported a series of cases of acute rheumatism complicated by endocarditis, myocarditis, and pericarditis, singly or together, in most of which he was able to isolate a delicate diplococcus, differing from any hitherto described, and unequivocally distinguishable from the various forms of staphylococcus, the streptococcus, and the diplococcus of pneumonia. The inference to be drawn is that this organism is the cause of acute rheumatism, and likewise of the secondary complications.

Anti-oleomargarin Laws.—The organized movement to prevent the sale of oleomargarin has received a fresh impetus from a recent decision of the United States Supreme Court sustaining a Massachusetts statute. Divested of the technical phrases in which lawyers so generally indulge, the decision is to the effect that the prohibition of the sale of oleomargarin, when colored to look like butter, is a legitimate exercise of State's rights, and not contrary to the constitutional provision against interference with inter-State commerce. The newspapers, as usual, are wide of the mark in criticising the decision. Apart from the control that the corporations manufacturing oleomargarin on a large scale have, by reason of the advertising or other patronage they may wield, many well-intentioned journals are not informed as to the facts. The court well said that the only reason that oleomargarin is made to look like butter is to deceive the unwary. Yet we are told in an editorial in a prominent daily that there is no longer any danger of deception, and if there were such danger the marks on the packages would prevent it. The fact is that oleomargarin almost never reaches the consumer except under the pretence of being butter. No man or woman buys it knowingly for his or her own use. Those who deal in it wholesale handle it without any sight of it mostly, but it is the pound-packages, delicately colored, and neatly wrapped in muslin or waxed paper, and with imprints simulating butter, which are eaten. These packages have no label or mark to tell their true nature, and most persons eat the substitute believing that they are getting real butter.

A Grave Defect in Zoologic Manuals.—At the recent meeting of the Association of American Anatomists in New York, Professor **BURT G. WILDER**, of Cornell, reiterated, under the title "Loose Characterizations of Vertebrate Groups," a criticism already made in 1880, and again in 1885, in his Address as Vice-President of the Biological Section of the American Association for the Advancement of Science, viz.: Among characters that are alleged to distinguish groups from one another, some may really be constant and peculiar; but others are constant and not peculiar; still others may be peculiar but not constant, and others neither peculiar nor constant. A marked instance of this confusion occurs in a recent authoritative English work. Besides tending to bewilder the student, and even mislead the naturalist, Prof.

Wilder held that this ambiguity, in such marked contrast to mathematic and even linguistic treatises, prevented the recognition of natural science as a means of mental training and as a requirement for admission to colleges. As a remedy he urged that all natural history courses should embrace the principles and practice of logic, and that writers of manuals and text-books, while not neglecting correctness and completeness, should pay more heed to clearness and consistency.

Horse-meat as Food.—Some time ago a brief editorial allusion was made in THE NEWS to the rumors spread in Germany that horse-meat was being used in the canned meats sent from America. An investigation resulted negatively, but the rumors are again current, even in papers in this country. Some "reliable unknown" has stated that in Chicago a regular business is carried on in preparing horse-meat to masquerade as beef. If this be true, the question naturally suggests itself as to what sanitary bearing the subject has. Probably the horse is a safer source of meat-food than the animal that yields our beef. Of course, the sale of one meat under pretence of it being another is a fraud, and should not be tolerated; but it will be an interesting inquiry to determine just what is the dietetic value of the meat of the horse, and to what diseases, if any, will its use give rise.

REVIEWS.

MEDICAL JURISPRUDENCE, FORENSIC MEDICINE, AND TOXICOLOGY. By R. A. WITTHAUS, A.M., M.D., Professor of Chemistry, Physics, and Hygiene in the University of the City of New York, etc., and TRACY C. BECKER, A.B., LL.B., Counselor-at-law and Professor of Criminal Law and Medical Jurisprudence in the University of Buffalo. In four volumes. Vol. ii. Large 8vo, 751 pages. New York: Wm. Wood & Co., 1894.

WE have already noted with approval the first volume of this extended treatise. The present instalment includes some most important and disputed topics in medical jurisprudence. Dr. Edward S. Wood discusses the subject of blood-stains and other stains. This chapter is freely illustrated by views of highly-magnified blood-corpuscles from man and various domestic animals, and Dr. Wood inclines to the possibility of positively identifying, under favorable circumstances, human blood-stains.

The section on railway injuries, contributed by Dr. W. B. Outten, covers nearly two-hundred pages. It is an exhaustive review of this important field; indeed, it seems as if a disproportionate space has been given to it. However, there can be no doubt that a very large portion of the practice of lawyers and medical experts is devoted to this class of cases, and a comprehensive presentation of the subject will be of great service. Much attention is given to methods of railroad operation and construction, signalling, etc.

The subject of unnatural vices is also discussed quite at length, and in the main more plainly than in most works of the class. The revelations as to the forms of vice observable in some American cities are startling. There seems to us to be no reason for the use of Latin phrases in the definition of special forms of unnatural vice. A work of this kind does not fall into the hands of boys and girls, or even of adults other than those who know how to use it. There can be no objection, therefore, in defining clearly in scientific English every term used.

The volume also includes chapters on abortion, infanticide, rape, pregnancy, sexual incapacity, and malingering.

TEXT-BOOK OF HYGIENE: A Comprehensive Treatise on the Principles and Practice of Preventive Medicine from an American Standpoint. By GEORGE H. ROHÉ, M.D., Professor of Therapeutics, Hygiene, and Mental Diseases in the College of Physicians and Surgeons, Baltimore. Third edition, thoroughly revised, and largely rewritten. Octavo, 553 pages. Philadelphia: The F. A. Davis Co., 1894.

ONE of the most striking additions to the present revision of Dr. Rohé's favorably-known book is a series of questions appended to each chapter, and constituting a review of the topics discussed in that chapter. We have no particular criticism to make as to the questions themselves. They have been prepared by a competent teacher, and are largely of that type known to lawyers as "leading." We cannot, however, regard the insertion of these questions as in the interest of the best teaching. That they will add to the popularity of the volume in some ways is undoubted; indeed, such insertions are likely to be suggestions by publishers rather than by authors. They lead to cramming and a study of the work merely with a view to prepare for examination.

Apart from this, we have no objection to make to the book. It has been thoroughly revised, especially the chapter on quarantine, which was prepared by Drs. Walter Wyman and H. D. Geddings, of the U. S. Marine-Hospital Service. The chapter represents fully the moderns method of maritime sanitation. Medical Director Gihon has revised the chapter on marine hygiene, and this is, of course, a guarantee of excellence.

The work is comprehensive in scope, and contains a large amount of information well expressed. In the uncertain or disputed field of public hygiene, such as the use of stimulants, the author expresses himself with due caution.

The book is well printed. Illustrations are not numerous. The present edition will undoubtedly sustain the reputation the book has attained.

A MANUAL OF THE PRACTICE OF MEDICINE. By A. A. STEVENS, A.M., M.D. Lecturer on Terminology and Instructor in Physical Diagnosis in the University of Pennsylvania; Demonstrator of Pathology in the Woman's Medical College of Pennsylvania. Revised edition. 8vo, pp. 490 and Index. Philadelphia: W. B. Saunders, 1894.

THE present edition of this manual, the third, has been issued within two years of its publication. Demand for a book is certainly an evidence that it meets a want and, to some extent, that it also has merit. The merit and the success of manuals such as this lie chiefly in the fact that they closely follow the more voluminous standard text-books and present their subject-matter uniformly classified and much condensed. It were an advantage, however, if occasionally the author were somewhat less conservative. In ten pages on the urine, of which nearly two are devoted to the determination of grape-sugar, the phenyl-hydrazin test, so valuable for its simplicity and sensitiveness, is not mentioned. Again, the diagnosis between varicella and variola is said to depend, among other things, on the absence of umbilication and inflammatory areolæ from the lesions of the former—one of those classic blunders that survive repeated correction.

Medical, Pharmaceutical, and Dental Register-directory and Intelligencer, for Pennsylvania, New York, New Jersey, Maryland, Delaware, and the District of Columbia. Third edition, pp. 836. Philadelphia: George Keil, Editor and Publisher, 1894.

This book contains the names of physicians, druggists, and dentists in the States mentioned, arranged alphabetically, and in the large cities also numerically by streets, the school and year of graduation, and office-hours in cities; a list of colleges, State societies, and national associations, asylums, homes, hospitals, dispensaries, etc., as well as the latest laws in these States. It should serve a useful purpose. Among many reputable advertisements we regret to see a number that are not so.

Essentials of Chemistry and Toxicology. By R. A. Witthaus, A.M., M.D. Twelfth edition. 16mo. 292 pages, and index. New York: William Wood & Co., 1894.

This is a student's pocket compend, the repeated editions of which have enabled its author to keep it up to the times. The present edition uses the revised spelling of chemic terms. It contains a large amount of information clearly expressed. We cannot, however, refrain from placing on record our disapproval of the question-and-answer system which the work employs.

Directory of Trained Nurses. Philadelphia: J. Albert Cornell, 1894.

This little book ought to subserve the useful purpose for which it was designed, that of bringing the nurse on the one hand in easy communication with patient and physician on the other hand.

CORRESPONDENCE.

FIN DE SIÈCLE MEDICAL SCHOOLS AND HOSPITAL MANAGEMENT.

To the Editor of The Medical News,

Dear Sir: As the century wanes, along with the plague of seventeen-year locusts and serpentine dancers, comes the advertising hospital.

The "regular" medical profession of New York, as you probably know, is, like Gaul, divided into three parts: "Old coders," who only consult with each other; "new coders," who consult with anybody, and "no coders," who—well, this name is hardly appropriate, for they have a code, conspicuous for its simplicity and comprehensiveness. It is "every man for himself and the devil take the hindmost;" and it begins to look as though the poor, East-side physician of New York was the one thus relegated to the caloric custody of the evil one.

The New York Post-Graduate Medical School and Hospital was located in a part of the city already well supplied with hospitals and dispensaries, and teeming with reputable and struggling medical men. It has recently completed and opened with considerable flourish "a large six-story, fire-proof structure, of 98 feet frontage, and 110 feet in depth, with accommodations for 195 patients and 250 matriculates," and a dispensary of unlimited capacity. Recent events seem to indicate that the hospital, in its new and fire-proof garb, is beginning to appreciate its redundancy, and one can almost hear the multitudinous attending staff clanking through the empty wards which should resound with the yelp of the colicky child, while the humble interne dodges behind, sniffling the air thus far at least aseptic.

Indications point to the babies' wards as the chief sufferers from vacuity and ennui; and who can think, without pain, of the spotless diapers, fluttering with suppressed desire to be the first on which some incipient Turner shall execute his maiden study in meconium yellow?

By indications, I mean advertisements in the daily press.

The *New York Daily News*, Thursday, December 6, 1894, contained the following advertisement:

"The babies' wards of the New York Post-Graduate Hospital, corner Second Avenue and Twentieth Street, are reopened for Medical and Surgical Diseases of Infants and Young Children (contagious diseases excepted); no charge to poor. Cases admitted by House Physician in Babies' Reception Wards of Dispensary Department between 9–12 A.M. and 5–6 P.M."

Then follows another advertisement for lying-in women, closing with the legend, "Doctors furnished at any hour, night or day," which reminds one of the card seen on ice-wagons, "Good work-horses to let by the day or week." This offer would seem to imply that East-side doctors were too busy to answer calls during the day, and either disconnected their door-bells at night or slept away from their offices in a palatial residence on Riverside Drive.

Now, these advertisements are no East-side joke, nor are they inserted to help along a struggling paper. The hospital needs babies to cheer its sunny, fire-proof wards with colicky coo and vivacious vomit, and something must be done also to limber up the long forceps and cephalotribe which hang rusting on their pegs.

Why this apparent dearth of vernal humanity? Why this coyness in a region where the very air is rendered fertile by gas-works and garbage-strewn streets?

If an advertisement the hospital must have, it is well placed, as in an adjoining column are advertisements of cheap midwives (?), "reliable on female irregularities," "successful in female complaints," who guarantee "perfect safety," "privacy," and, much to the disadvantage of the hospital, "adoption of infants." In the column on the other side, "Old" Drs. Smith, Gray and Grindle, and Drs. Hallett and Hawker make promises which no incorporated institution can rival or equal. They guarantee to strengthen "weak organs," to render plump "shrunken organs," and to magnify "undeveloped organs." They promise to restore "vigor" and "lost manhood;" they correct "errors of youth," and remove "impediments to marriage," as well as "shyness" and "blotches."

It strikes me the hospital is handicapped at the start by its neglect to promise the "adoption of infants" and the sure cure of "scalding" and "trembling," "red-spots" and "restless nights."

To apologize for advertising on the plea of informing the poor of the purposes of the hospital would be disingenuous. The poor and, still better, the medical beats of New York know full well the uses of hospitals and dispensaries, and are also sharp enough to take advantage of the premium on clinical material. Few patients, particularly if they have an interesting complaint, need pay for expert advice or treatment nowadays, so numerous and hungry are the various clinics. The forty-eight hospitals of New York City do not advertise, yet in 1893 they treated in their wards 78,945 patients. Neither do the thirty-three dispensaries advertise, except for charitable contributions: still, in 1893, they treated 626,160 patients, showing conclusively that the class for which charitable medical institutions are built need not be told their purpose in the daily press.

There are too many hospitals and dispensaries in our large cities; too many clinical professors. There is too much injudicious and undeserved medical charity. If a hospital cannot be filled without illegitimate advertising, it should be shut up. If a starving doctor should openly advertise, the Committee on Ethics of some Pharisee Medical Society would at once brand him as unclean, and he would be shunned by his fellows as a leper. But a *body* of doctors can illuminate the ash-barrels, dead-walls, and curbstones of a whole city with their posters, and can invade the advertising columns of the poor man's paper, alongside of abortionists, clairvoyants, and quacks, but to this the Committee on Ethics is blind. But why not? since in Committees on Ethics are generally to be found some of the most flagrant ethical offenders!

Little redress will the East-side physician be likely to get; but let him soliloquize with Cheney—

> "Who drives the horses of the sun
>   Shall lord it but a day;
> Better the lowly deed were done,
>   And kept the quiet way."

R. W. AMIDON, M.D.

19 WEST TWENTY-FIRST STREET, NEW YORK CITY.

SCARLATINA AND MEASLES IN THE SAME PATIENT.

To the EDITOR OF THE MEDICAL NEWS,

SIR: I desire to report a case of scarlatina complicated by measles, similar to that cited in your issue of December 29, 1894, as reported by Ferguson in the *British Medical Journal.*

On June 10, 1894, I was called to see a girl, eight years old, whose neck, chest, arms, etc., I found covered with a diffuse scarlet exanthem, and who also had a moderately-severe angina, with elevation of temperature, appearance of tongue, and other symptoms peculiar to scarlatina.

After two or three days the eruption faded, desquamation became well established, and the child progressed favorably. On the ninth day the face, neck, chest, and arms became the seat of a typical papular eruption of measles, the temperature and pulse rising slightly, with coryza and cough, though the symptoms were decidedly less severe than are usually found in uncomplicated measles. In spite of this unpleasant feature the child made an excellent and uninterrupted recovery and with no sequel.

The question that arose in my mind was, What was the source of infection? I excluded the nurse and myself, the only two in attendance upon the child; the former because she was constantly with the little patient, and myself for the reason that I had no case of measles under my care at the time, nor for some time before.

Respectfully,

G. A. HIMMELSBACH.

137 W. TUPPER STREET, BUFFALO, N. Y.

NEWS ITEMS.

Collective Investigation upon the Operative Treatment of Malignant Neoplasms of the Larynx.—With the object in view of securing sufficient data to lead to an intelligent conclusion on a number of doubtful points in the treatment of malignant neoplasms of the larynx, Dr. Johann Sendziak, 139 Marzatkowsk Strasse, Polish Russia, has issued an appeal to laryngologists and surgeons soliciting replies to the following questions:

1. Name and address of the operator.
2. Age and sex of the patient operated on.
3. General condition of the patient. (Were the lymphatic glands affected or not?)
4. Laryngoscopic image. (Right or left side?)
5. Diagnosis (clinical or microscopic).
6. Date of operation (day, month, year).
7. Character of operation (endolaryngeal, thyreotomy, total or partial laryngectomy).
8. Result of operation (cause of death; recurrence—when? Recovery. Date of last examination or last report).
9. Source of report or unpublished case.
10. Remarks (general views, etc.).

Medical Society of the State of Pennsylvania.—The members of the Medical Society of the State of Pennsylvania who wish to read papers at the meeting to be held at Chambersburg, May 21–24, 1895, are requested to send their names and the titles of the papers to the chairman of the Committee on Scientific Business, Dr. Charles W. Dulles, 4101 Walnut Street, West Philadelphia.

The committee desires papers to be *absolutely* no longer than ten minutes.

At the last meeting a large number of interesting papers were not read because those preceding them were too long, and it is to be hoped that those who prepare papers for the coming meeting will condense them *as much as possible.* The laws of the Society permit each writer to occupy twenty minutes, but it is thought that it will be of advantage if the members of the Society do not avail themselves of all their privilege.

To Philadelphia Bacteriologists: The Councils of the city of Philadelphia having appropriated fifteen thousand dollars for the purpose, it is the intention of the Board of Health to establish a Bacteriological Laboratory.

Under the law governing appointments in Philadelphia, the Bacteriologist and Assistant Bacteriologist must be selected from a Civil Service eligible list. The undersigned have been appointed by the Mayor as an Examining Board for the purpose of the examination, which will be held in about two weeks. Meanwhile blank applications can be had at the office of the Director of the Department of Public Safety, Room 217, City Hall.

The salaries to be paid are, under the appropriation ordinance, to be fixed by the Board of Health and the Mayor, whose desire it is to secure competent men without regard to the salary to be paid.

It is hoped to conclude the examination in one day.

E. O. SHAKESPEARE, M.D.,
W. M. L. COPLIN, M.D.,
ERNEST LAPLACE, M.D.

The Third International Dermatological Congress will not be held this year, as proposed. The time of meeting has been postponed. because the British Medical Association meets in London this summer, and it was feared by the Executive Council of the Congress that the autonomy and international character of the Congress would be imperilled by holding its meeting at the same time and place, as well as that the necessarily divided interests of the British dermatologists would prevent that full exercise of hospitality to their foreign visitors that they so much desire to extend. As the next meeting of the International Medical Congress will be held in Moscow in 1896, it is possible that the Dermatological Congress may not be held until 1897.

Testimonial to Sir Henry Acland.—It is proposed to make the retirement of Sir Henry Acland from the Regius Chair of Medicine in the University of Oxford the occasion of a memorial to be devoted toward increasing the usefulness of the Sarah Acland Home for Nurses, an institution that provides district nurses and medical appliances for the poor, and maintains private nurses and a medical and surgical home to which patients unable to afford the ordinary fees are admitted on a reduced scale of charge. It is hoped that a fund of £10,000 can be raised; £1055 have already been subscribed.

The Honorary Treasurer of the Fund is the Warden of All Souls' College, at Oxford.

Dr. William Osler, according to late report, has been offered the Presidency of McGill University. We are highly pleased to state that Dr. Osler will not leave Johns Hopkins, and his hosts of friends in the States will be delighted to learn of this determination; indeed, medical men everywhere will be equally glad to know that medical science, which he has enriched with his genius, is not to be deprived of his most valuable service.

Intercollegiate Foot-ball.—The presidents of Indiana colleges, at a recent conference in Indianapolis, decided to prohibit intercollegiate foot-ball contests between the students of the institutions over which they preside.

Prize-essay on Tuberculosis.—Dr. Herman Weber, of London, has given the Royal College of Physicians $12,500 for the foundation of a prize to be offered every two or three years for the best essay upon tuberculosis.

Science.—The publication of this popular and useful journal has been resumed, and its direction placed in the hands of a staff of earnest and competent workers in different departments of scientific research.

The Pennsylvania State Board of Medical Examiners will meet on February 14, 1895, in Philadelphia, at the northwest corner of Broad and Pine Streets, to examine applicants for license to practise medicine in the State.

Physician to Howard Hospital.—Dr. Alfred Stengel has been elected physician to Howard Hospital, succeeding Dr. F. M. Luther, who resigned.

Dr. d'Arsonval has been appointed to the chair of medicine in the College de France, in succession to the late Prof. Brown-Séquard.

The Practitioner.—Dr. Malcolm Morris has succeeded Drs. Lauder Brunton, Donald MacAlister, and Mitchell Bruce in the editorial conduct of the *Practitioner*.

The Internationale Klinische Rundschau is hereafter to be known as the *Wiener klinische Rundschau*.

Prof. Wolfler, of Gratz, has been elected to the chair of surgery in the University of Prague.

ORIGINAL ARTICLES.

AINHUM.[1]

BY WALTER L. PYLE, A.M., M.D.,
OF WASHINGTON, D. C.

AINHUM may be defined as a pathologic process, the ultimate result of which is a spontaneous amputation of the little toe. It is confined almost exclusively to negroes, chiefly males, and of African descent. In Brazil it is called "ainham" or "quigila." "Ainham" literally means to saw, and is doubtless a colloquial name derived from a supposed slow, sawing process. The Hindu name for it is "sukha pakla," meaning dry suppuration.

In 1866, da Silva Lima, of Bahia, at the Misericordia Hospital, gave the first reports of this curious disease, and for quite a period it was supposed to be confined to Brazilian territory. Since then, however, it has been reported from nearly every quarter of the globe. Relative to its geographic distribution I will make a brief summary of reports from different localities:

South America. Da Silva Lima and Seixas, of Bahia, have reported numerous cases in Brazil, as have Figueredo, Pereira, Pirovano, Alpin, and Guimares. Toppin reports it in Pernambuco.

Egypt. Mr. Milton reports a case from Cairo, and Dr. Creswell at Suez, both in slaves.

Trinidad. E. A. G. Doyle reports several cases at the Fernando Hospital.

African Coast. Digby reports its prevalence on the west coast of Africa, particularly among a race of negroes called Krumens. Messum reports it in the South African Republic, and speaks of its prevalence among the Kaffirs. Eyles reports it on the Gold Goast. It has also been seen in Algiers and Madagascar.

India. Through the able efforts of Her Majesty's surgeons in India the presence of ainhum has been shown in India, and considerable investigation made as to its etiology, pathologic histology, etc. Wise at Dacca, Smyth and Crombie at Calcutta, Henderson at Bombay, and Warden, Sen, Crawford, and Cooper in other portions of Southern India have all rendered assistance in the investigation of ainhum.

In *China* a case has been seen, and British surgeons speak of it as occurring in *Ceylon.*

British Guiana. Von Winckler presents an admirable report of twenty cases at Georgetown.

St. Thomas. Dr. Potoppidan sends a report of a case in a negress.

The disease has several times been observed in *Polynesia.*

North America. Dr. Hornaday reports a case in a negress from North Carolina, and, curious to relate, O. Horwitz, of Philadelphia, and Shepherd, of Canada, found cases in negroes both of North Carolina antecedents. Dr. James Evans reports a case in a negro, seventy-four years of age, at Darlington, S. C. Dr. R. H. Days, of Baton Rouge, La., had a case in a negress, and Dr. J. L. Deslates, also of Louisiana, reports four cases in St. James Parish. I have seen a case in a negress, aged fifty years, in Washington at the Emergency Hospital.

The foregoing summary shows the universal distribution of the disease, the Arab, Hindu, Mussulman, and even the Mongolian being susceptible as well as the negro.

So prevalent is the disease in India that Crawford found a case in every 2500 surgical cases at the Indian hospitals. The absence of pain or inconvenience in many instances doubtless keeps the number of cases reported few, and again we must take into consideration the fact that the class of persons afflicted with ainhum are seldom brought in contact with medical men.

Ainhum is a much more common disease than has heretofore been supposed, and as such deserves a careful consideration.

The disease usually affects the fifth phalanx at the inter-phalangeal joint. Cases of the fourth and other phalanges have been reported. Cooper speaks of a young Brahmin who lost his left great toe by this process. Crombie speaks of a simultaneous amputation of both fourth toes. Potoppidan reports a similar case in a negress on St. Thomas Island. Sen reports a case in a supernumerary digit in a child, whose father, a Hindu, lost a toe by ainhum. Eyles reports a case in a negro in whom the second finger was affected. Mirault, at Angiers, speaks of a case in which two fingers were lost in fifteen days, a fact which makes his diagnosis dubious. Beranger-Ferrand has seen all the toes amputated, and there is a wax model by Baretta, Paris, in the Army Medical Museum at Washington, in which all the toes of the right foot have been amputated, and the process is fast making progress at the middle third of the leg.

---

[1] Read before the Pathological Society of Philadelphia, November 8, 1894.

Ainhum is much more common in males than in females; it is in fact distinctly rare in the latter. Of Von Winckler's twenty cases all were males. It may occur at any age, but is most common between thirty and thirty-five. It has been reported *in utero* by Guyot, and was seen to extend up to the thigh, a statement that is most likely fallacious. However there are well-authenticated cases in infants, and again in persons over seventy years of age.

In some few cases the metatarso-phalangeal joint is affected; but no case has been seen at the base of the ungual phalanx.

The duration of the disease is between two and four years, but Dr. Evans' case had been in progress fifty years. It rarely runs its full course before a year.

Reports conflict as regards the influence of climate on this disease. Wise, at Decca, says it is most common in damp or rainy weather, while Crombie and Smyth, also in India, report cases from the dry highlands associated with goiter. Climate, perhaps, has no influence on it. Dry, hard ground causes more pain in walking, and the dry cold winds, spoken of by Crombie, exert their influence indirectly in this manner.

There is a difference of opinion again regarding the soil favorable for its development. Sandy soil is reported to be a cause, and the Egyptian reports attribute it to working in salt. Seixas, of Bahia, an authority, says the wearing of boots does not prevent it. Weight-carriers are most affected, particularly on a hard soil, according to some Indian observers. We can, therefore, form no definite conclusion as to the influence of soil outside of the extra pain caused by walking on a hard soil.

Symptoms. Ainhum begins as a small furrow or crack, such as soldiers often experience, at the digito-plantar fold, seen first on the inner side. This process of furrowing never advances in soldiers, and has been given a name more expressive than elegant. In ainhum the toe will in a few days swell, and a pain, burning or shooting in nature, may be experienced in the foot and leg affected. Pain, however, is not constant. There may be an erythematous eruption accompanying the swelling. The furrow increases laterally and in depth, and meets on the dorsal aspect of the toe, giving the toe the appearance of being constricted by a piece of fine cord. As the furrow deepens the distal end of the toe becomes ovoid, and soon an appearance as of a marble attached to the toe by a fibrous pedicle presents itself. By this time the swelling, if any, has subsided. The distal end of the toe bends under the foot, and becomes twisted when walking, and causes inconvenience, and, unfortunately, says Eyles, it is in this last stage only that the Fanti presents himself. There is in the majority of cases a small ulcer in or near the digito-plantar fold, which causes most of the pain, particularly when walked on. This ulcer does not occur early, and is not constant. The case under my observation showed no ulceration, and was absolutely painless, the negress applying for diagnosis rather than treatment. The furrow deepens until spontaneous amputation takes place, which rarely occurs, the patient generally hastening the process by his own operation, or by seeking surgical treatment. A dry scab forms at the furrow, and when picked and repicked constantly re-forms, being composed of horny desquamation or necrosis.

The *histology* of ainhum shows it to be a direct ingrowth of epithelium, with a corresponding depression of surface due to a rapid hyperplasia that pushes down and strangles the papillæ, thus cutting off the blood-supply from the epithelial cells, causing them to undergo a horny change. We are indebted to C. H. Eyles for the best description of the histologic change as observed microscopically.

The disease is not usually symmetrical, as formerly stated, nor is it simultaneous in different toes. There are no associated constitutional symptoms, no tendency to similar morbid changes in other parts, and no infiltration elsewhere. There is little or no edema with ainhum.

Crombie made measurements of the circumference of both the left and right toes in a case of ainhum, as follows: Circumference at bottom of furrow, right, 1⅞ inches; left, 1¼ inches. Circumference of distal phalanx, right, 2⅛ inches; left, 2⅞ inches. This demonstrates the lack of symmetry of the morbid process.

As a rule, sensation is not destroyed, although cases of anesthesia have been reported. There is usually no change in the nail. Weber compares the appearance of the distal end to a diminutive potato. The dorsal tendon stands out as a white cord, surrounded by a black ring. Eyles made his studies in a section hardened in Müller's fluid, and stained *en masse* in picro-carmin or eosin. The changes resemble somewhat the morbid process seen in lupus. The hypertrophy of the epidermis at the tip approximates one mm. in thickness, while that near the constriction equals 5 mm. in thickness. In the stratum corneum there is seen an hypertrophy of the interpapillary process, which is irregular. In the stratum lucidum the hypertrophy is uniform, and this layer in the posterior portion of the section becomes fused into the layer above. Instead of the characteristic appearance of an indistinct layer ot two or three cells deep, we see a layer of distinct cells twelve or fifteen deep.

Hypertrophic change is seen in the stratum granulosum also. In the stratum malpighii, anteriorly, while the interpapillary processes increase in all dimensions, slender processes, composed of double columns of closely-apposed pigmented (germinal) epithelium are seen which pass down, splitting the papilla. As the stage of separation advances these processes, which are formed by the evolution of the germinal layer covering the top of the papilla, give off shoots that coalesce with shoots of adjacent processes, and a network is formed, the trabeculæ of which consist of double layers of pigment-cells. Eyles describes the appearance on transverse section as a sheet of more or less typical prickle-cells, which is perforated by round or oval islets of papillary material, each islet being surrounded by a single layer of pigmented epithelium. Posteriorly, the entire thickness resembles the stratum corneum; the only foreign representative is a layer of pigment-cells, which may take the form of dim processes or form a small network. As to dermal or sub-dermal changes, there is seen a hyperplasia of fibrous tissue, subsequent to chronic inflammation. As concerns vascular changes, the larger arteries show an increase in adventitia, but little change in the muscular coat, though proliferation of connective-tissue elements may increase it. The intima is subject to a process similar to an endarteritis obliterans, which decreases or obliterates the lumen. As the vessels become smaller or capillary they are surrounded, if anteriorly, by a small round-cell infiltration, or, if posteriorly, by fibrous tissue. The section of the specimen can thus be distinguished. The capillary loops undergo a hyaline change, and there is fusion of the endothelial plates. In the veins the adventitia and endothelium are swollen. As to glandular changes, Eyles' observation showed a thickening occasionally of the membrana propria by the addition of white fibrous tissue. There may be fatty change in the distal end of the coil, and the lumen becomes less.

The osseous changes consist in a rarefying osteitis, which advances regularly from the periosteum, but irregularly toward the center. There is little attempt at new bone-formation, and cavities are formed which eventually become filled with a reticulum of delicate fibrous tissue, capillaries, and oil-globules. There is a gradual conversion into fibrous tissue.

Eyles made little or no observation of nerve-changes; but there is doubtless a process identical with that seen in neuritis of any duration.

The similarity to epithelioma is seen by the foregoing description; but there is no infiltration or epithelial hyperplasia at the side or in the vicinity of the furrow, this being confined to the deepest portion.

In ainhum there is, first, simple hypertrophy, then active hyperplasia. The papillæ are pushed down and deprived of blood-supply, and undergo horny change. Meanwhile the pressure thus exerted on the nervivasorum sets up vascular changes which bring about epithelial changes in more distant areas, the process advancing anteriorly, that is, in the direction of the arteries. This makes the cause, according to Eyles, an inflammatory and trophic phenomenon due mainly to changes following pressure on the vasomotor nerves.

Etiology. The theories of the causation of ainhum are quite numerous, and I will take them up individually.

The influence of soil and climate has already been discussed

The first cause is the admirable location for a furrow in the digito-plantar fold, and the excellent situation of the furrow for the entrance of sand or other particles to make the irritation constant, thus causing chronic inflammatory changes, which are followed subsequently by the changes peculiar to ainhum.

The cause has been ascribed to the practice of wearing rings on the toes; but von Winckler says that in his locality (British Guinea) this practice is confined to the coolie women, and in not one of his twenty cases had a ring been previously worn on the toe; in fact, all of the patients were males. Digby says, however, that the Krumens, among whom the disease is common, have long worn brass or copper rings on the fifth toe. Again, the natives of India, who are among those most frequently afflicted, have no such custom.

Injury, such as stone-bruise, has been attributed as the initial cause, and well-authenticated cases have been reported in which traumatism is distinctly remembered; but Smyth, Weber, and several other observers deny that habits, accidents, or work, are a feature in causation. The case I saw gave no history of traumatism.

The American observers of most recent date advance the theory of pathogenic organisms; but the immunity of people not dark-skinned seems to contradict this, together with the fact that there is no history of contagion in ainhum. Collas say the disease is amputating leprosy, but the fact of its being localized and the absence of constitutional symptoms contradict this theory. The affection has been called pityriasis Ethiopium and scleroderma annulare. Frontau denies its existence as a distinct disease.

To summarize, none of the theories advanced bears discussion but that of Eyles, and, from my own observation of the process, there is pressure of the hypertrophied fibrous tissue subsequent to continued irritation on the vaso-motor nerves, to which pressure the peculiar morbid changes of ainhum are due. It is really a tropho-neurosis. Heredity seems to exert little influence.

The diagnosis is easy. No other disease resembles it. Gangrene is distinctly different. In frost-bite there is a history of cold, and this affection is of short duration.

The absence of constitutional symptoms and its limited field of occurrence distinguish ainhum from leprosy and from elephantiasis.

I have compiled a list of all the existing literature of the subject in the Surgeon-General's Library at Washington, and herewith append it.

TROPHIC LESIONS OF THE JAWS IN TABES DORSALIS.

BY LEO NEWMARK, M.D.,
OF SAN FRANCISCO, CAL.;
PHYSICIAN TO THE SAN FRANCISCO POLYCLINIC.

TROPHIC changes in the jaws have been much less frequently observed in tabes dorsalis than the disturbances in the nutrition of the joints and the bones of the extremities which so interestingly vary the course of that most common disease of the spinal marrow. Although the first observations of a tabetic maxillary affection were published as long ago as 1868, a German author[1] in 1891 was not able to collect more than twenty-two cases. All of these were gathered from the French and German literature. Brief mention of the loss of teeth may occasionally be met in some English or American work, but no description of the typical tabetic disease of the jaw is presented. It is therefore hoped that the following account of a case which was observed at the San Francisco Polyclinic will not be deemed superfluous.

The patient, a man forty-three years of age, came under observation February 6, 1894, complaining of shooting pains in the lower extremities. Twenty years ago he had three or four soft venereal sores followed by suppurating buboes. No syphilitic symptoms supervened. During eighteen years of married life his wife had been well and had borne him three children, two of whom still live and are healthy, while the other died at fourteen years of some acute disease. About eight or nine years ago there were two miscarriages.

The patient was in good health until about seven years ago, when he was seized with his present disease—rather acutely, according to his account. While lifting a heavy piece of lumber he felt something give way in his back, and was unable to stand upright for several days thereafter. Then he staggered in walking, his legs yielded, and his thighs felt numb. A week after the injury there was complete retention of urine, and the catheter had to be passed during five or six weeks. The bladder gradually recovered to a great extent, but some weakness of the urinary current has persisted. For several years past he has experienced no normal desire to micturate, and passes his water at regular intervals, not in response to any stimulus, but as a matter of habit and prudence. When worried he is compelled to have recourse to the catheter. The bowels gave no cause for complaint.

---

[1] Rosin: Deutsche Zeitschrift für Nervenheilkunde, 1891, Bd. i, p. 532. This writer collated the cases reported up to that date and appended a bibliography to his article; but his list is not quite complete. Since then Hudelo has recorded a case in Annales de Dermatologie et de Syphiligraphie, May, 1893, and Wickham has republished this case and added another in the same journal for January, 1894. A review of several French cases, most of which are referred to by Rosin, will be found in a paper entitled "Les Altérations Dentaires au Cours du Tabès," by Lemarié and Albert Bernard in L'Odontologie, February, 1894; a translation of this paper is contained in the Pacific Coast Dentist for May, 1894. In his contribution to the jubilee-volume of the University of Halle ("Ueber traumatische Tabes," etc., 1894; page 27 of the reprint), Hitzig gives a brief account of a tabetic patient observed in 1870 who had been affected in 1863 with the jaw-disease now under consideration. A case is mentioned by Gowers in his Manual of Diseases of the Nervous System, second American edition, vol. i, p. 411.

For over two years after the time from which he dates his disease he had pain in the small of the back, and needed the support of a cane in walking. When the pain ceased and his gait improved the lightning-pains began in the legs and in the sides of the trunk, sometimes darting up into the left arm-pit, and they have continued to torment him frequently. There is no girdle-sensation. Sexual power is abolished. There have been neither laryngeal nor gastric crises. Vision is not disturbed. Some care is required to "regulate his walk," especially when descending stairs.

Incidentally the patient remarked that, although he had never suffered from toothache, he had in the course of the last three or four months lost thirteen of his upper teeth. He had previously had slight neuralgia in the right cheek and temple. The falling out of the teeth was quite painless and attended with very little or no bleeding. Thus, while eating, he would become aware that a tooth was loose, would easily extract it with his fingers, and then proceed with his meal, or the tooth would not even require "picking" (as the patient termed it), but fell spontaneously into his mouth.

He furthermore related that two pieces of bone had recently been painlessly cast off from the left side of the upper jaw.

In the course of his illness this man had taken a considerable quantity of drugs, among them potassium iodid, especially during the last two years, but he has not had stomatitis nor been salivated.

On the 6th of February the patient was described as a gray-haired individual of medium height. A large cicatrix in the right groin was the only reminder of the venereal infection. His gait was not conspicuously ataxic, but the usual tests disclosed a moderate degree of incoördination in the lower limbs. Romberg's symptom was quite marked. There was the Argyll-Robertson pupil, and the left pupil was larger than the right. The knee-jerks were absent, as were also the plantar reflexes. The cremasteric reflex was faint on either side; the abdominal reflex was present and brisker on the right than on the left side, being rather excessive on the former; the right abdominal reflex could be provoked by stroking the upper part of the anterior and inner surfaces of the right thigh, as in the manipulation employed to produce the cremasteric reflex. There was slight anesthesia at the outer and inner borders of the feet and on the outer surface of both thighs; the anesthesia was more marked in the right gluteal region. Sensation was said to be less acute in the left half of the abdominal surface than the right, but this difference was purely subjective.

There was no anesthesia or ataxia in the upper extremities. The triceps reflex was not obtained; the periosteal reflexes of the forearm were present. Sensibility in the face was normal. The special senses were unimpaired. Thirteen teeth of the upper jaw were missing; only the two central incisors and the right wisdom-tooth remained. The lower set was complete.

In that part of the left superior maxilla from which the two fragments of bone mentioned by the patient were eliminated the gum[1] was swollen and lacerated, exposing the bone and secreting pus. This region, as well as the rest of the upper gums, was insensitive to pain; prodding the mucous membrane with hot needles or tapping on the exposed bone produced no discomfort. There was much tartar on the lower teeth, and the gums were irritated; the two central incisors were somewhat loose and tender. This was the first time the patient had ever experienced anything like pain in a tooth. Apart from this, there seemed to be some analgesia of the lower gums also. Sensation in the tongue and mucous membrane of the cheek was preserved, also in the nasal mucosa.

On the 26th of February the patient reported that a few days before he had felt something loose in the left side of the upper jaw, and with his tongue had dislodged a third piece of bone, which he brought for inspection. The exfoliation of this sequestrum was perfectly painless. The sequestrum contained an alveolus. After this event the erosion of the gum promptly began to heal, and in a short time only a depression in the alveolar process marked the site of the necrosis. One of the lower incisors, which was loose and tender, was extracted at about this time by a dentist, as it projected beyond the line of the teeth, and was deemed superfluous. Its extraction was stated to have been quite painful. It is well to emphasize the fact that this trouble in the lower jaw was solely due to the accumulation of tartar. There has been no disturbance since.

Until nearly the middle of May there was no further alteration in the patient's dental condition. Then another breach was made in his ἕρκος ὀδόντων, for the two remaining upper incisors became loose, and he "picked" one of them himself without pain or bleeding, while a dentist removed the other with almost equal ease. Soon the same process was established at the site of these teeth as had previously taken place on the left side of the upper jaw, and on the 7th of June a fragment of bone was exfoliated. After this the lesion of the gum quickly healed.

On the 11th of June the patient complained of pain on the inner side of the right cheek, opposite the molars. Inspection revealed the presence of an ulcer of the gum, extending forward from the last molar about an inch, and invading laterally the mucosa of the cheek, but displaying no tendency to spread toward the hard palate. The ulcer was quite pale and torpid; excepting where it encroached on the cheek it was analgesic; it exposed the bone, which was evidently necrotic, and secreted considerable pus.

At this stage of his disease the man was shown to several dentists who had convened in San Francisco to attend the Mid-Winter Fair Dental Congress. A number of the teeth which had been shed were carefully examined and pronounced sound. It was established that their falling out was not due to pericementitis, pyorrhœa alveolaris, or any other process with which dentists ordinarily have to deal. Dr. William J. Younger, a dentist of more than national reputation, testified that this maxillary disease was all but unique in his very extensive experience.

---

[1] It had been subjected to dental treatment before the patient came to me.

No palpable fragments of bone were cast off from this ulcer, but the alveolar process was nevertheless undergoing disintegration, for soon a probe entered the antrum through the ulcer without encountering resistance. Many weeks elapsed before a tendency to heal became manifest. Finally, however, the gums closed again over the bone, leaving a long delicate cicatrix over the depression in the alveolar process and a small opening leading into the antrum.

On the 25th of June the right wisdom-tooth dropped out, and the denudation of the upper jaw was now complete. A sharp-pointed instrument inserted into the socket of the tooth provoked no pain. It was now about nine months since the "devastation had begun," but not yet was the "business of destruction done."

In the beginning of July, long before the ulceration of the gums on the right side had healed, a small ulcer appeared in the gum on the left side of the upper jaw at about the site of the last molar. This erosion gradually extended forward until it reached the locality of the left lateral incisor. It was pale, atonic, and analgesic. Like its companion on the other side of the jaw, it occupied the external half of the alveolar ridge, tending to invade the cheek, but avoiding the roof of the mouth. The bone was exposed, and there was a discharge of thin pus. No fragments of bone were eliminated, but there was evident osseous decay, for soon the antrum was opened. It was not until the middle of October that this ulceration had healed, leaving a still larger depression in the alveolar process than had been produced by the necrosis in February, and the fistula of the antrum.

At present (in the last week in October) no destructive process is visible in the jaw, but a recurrence must be apprehended.

Although not pertinent to the subject under immediate consideration, the patient's clinical history may be supplemented by adverting to an event of the 28th of June. On the morning of that day, as he was about to board a street-car, his left leg suddenly gave way at the knee; it felt "as if weighted with a ton," and seemed devoid of sensibility. When seen in the afternoon, the patient's gait was very unsteady, and he was forced to support himself on a cane; the ataxia was now quite marked, but it was much more conspicuous in the left leg than in the right. Tactile sensation was not so profoundly altered as the patient's account might have led one to suppose, but it was somewhat blunted in the left lower leg and foot as compared with the right; there was a distinct reduction of electro-cutaneous sensibility in the former; the retardation in the conduction of painful and thermic impressions amounted to five seconds in the left foot and three seconds in the right; and the muscular sense was now greatly disturbed in both lower limbs, but especially in the left one. There was also some loss of power in the left foot, but the muscles reacted well to the faradic current. Romberg's symptom was more marked than before.

With this acute onset, or at least sudden increase, of incoördination, there came a cessation of the lightning-pains. The appetite, sleep, and digestion improved, and the patient was enabled to resume his work (as a distributer of quack-advertisements!).

Unfortunately, during the cool weather prevailing in the middle of August the pains recurred with all their former severity. Then the disturbance in the leg began to abate, and examination a month later disclosed decided improvement in regard to the steadiness of the gait and some diminution of the other symptoms. The patient now walks without any support; but the lightning-pains continue to torment him.

The subjective and objective symptoms as herein set forth are sufficient to establish the diagnosis of tabes dorsalis.

With respect to the changes in the jaw and the loss of teeth, this case conforms on the whole to the manner in which these disturbances took place in the majority of cases reported in neurologic literature. A survey of all the accessible records, however, shows certain variations in the extent and the rapidity of the destructive process, as well as differences with regard to the period of tabes in which the maxillary disorder may supervene.

The immunity of the lower jaw in the present instance is worthy of note. In no case does the disease appear to have involved the lower jaw before the upper had been affected. Either both jaws are seized simultaneously, or (as in the larger proportion of cases) the upper becomes diseased first. Years may elapse between the onset of the trouble in the upper jaw and the implication of the lower.

As has been said, the shedding of the teeth and the destruction of the bone progress with variable rapidity. A few teeth having dropped out, and a necrotic fragment of bone having been exfoliated, a pause may succeed, lasting in some instances for years, before more teeth and more of the substance of the jaw undergo the same fate; or the denudation of the jaw may be completed in a very short time; thus, in one instance,[1] two weeks sufficed to deprive the upper jaw of all its teeth; and Gowers[2] tells of a patient who found that all his upper teeth fell out in the course of three days, without any pain or decay.

The maxillary disease may appear at any stage of tabes dorsalis. In some instances over twenty years had elapsed since the onset of the latter; in others fifteen, ten, seven, and four years respectively, and one individual is related by Hoffmann to have lost all his upper teeth in the characteristic way over one year and a half prior to the first typical manifestations of tabes.

---

[1] Hoffmann: Berliner klinische Wochenschrift, 1885.

[2] Manual, I, p. 411.

The dropping out of the teeth is sometimes unattended with necrosis of the jawbone. In two such cases the patients were affected also with the loss of their nails, and in another there was a perforating tabetic ulcer of the foot.[1]

In Wickham's paper on "Ulcérations buccales tabétiques" (*Annales de Dermatologie et de Syphiligraphie*) a patient is described who was afflicted with three perforating plantar ulcers, two on one foot and one on the other. This individual had lost in a comparatively short time, without pain, all his upper teeth and a number of his lower teeth, and the alveolar process was atrophied. There was on the alveolar border of the upper jaw a large, indolent ulcer apparently like those seen in my patient, but evincing a tendency to extend toward the roof of the mouth; it was anesthetic and penetrated to the bone, and Fournier, considering it to be of the same nature as the perforating ulcers of the foot, proposed to call it "*mal perforant buccal.*" In another case observed by Wickham and previously reported by Hudelo, this same maxillary affection was not associated with trophic lesions in any other part.

As far as can be judged from the description, there seems to be no essential difference between these "ulcérations buccales tabétiques" and those which in my patient exposed the bone. It has been seen that the latter are not necessarily associated with the elimination of appreciable fragments of bone, although the bone at the base is decayed, and that they ultimately heal in one part, while others form in other localities. We may agree with the statement of Wickham that the characteristics of these lesions are well marked; indeed, they are so pronounced that Fournier was enabled in the second case which he encountered to diagnosticate tabes simply by inspection of the mouth.

I have not been able to ascertain any instance in which this affection of the jaws accompanied any other nervous disease than tabes dorsalis.[2] Nor does it seem to occur as an independent disorder, and its distinction from the effects of phosphorus, actinomycosis, and other agents deleterious to the jaws and teeth meets with no difficulty. Syphilis, which is credited with so preponderant an influence in the production of tabes, cannot be held directly responsible for this jaw-disease associated with tabes, and we have Fournier's authority for the statement that Hudelo's case was not syphilitic.

Atrophy of the jawbones, especially the upper, and loss of teeth, may occur also in facial hemiatrophy, but the course and the attending circumstances are different in the two disorders. Their pathology, however, may be fundamentally identical, both being the supposed result of impaired trophic influence of the fifth nerve. It is interesting in this connection to note the coincidence of facial hemiatrophy and tabes dorsalis in a case reported by Jolly.[1]

The fifth nerve has been found affected in its trunk, ganglion, roots, and nuclei in various cases of tabes which had presented symptoms in the area of its distribution during life. But the only necropsies of cases in which the tabetic jaw-disease was among these symptoms are those recorded by Demange,[2] who made an anatomic examination of an individual who, about the fifteenth year of his tabes, had lost in less than two months all the teeth of his upper jaw, one after the other, in the characteristic manner; there was marked inflammation of the trigeminal nerves and atrophy of their bulbar nuclei. In another case observed by the same writer all the upper teeth on the left side had dropped out in the course of a month, while those on the right side were almost intact.[3] The autopsy disclosed atrophy of both fifth nerves, that of the left greatly exceeding that of the other, and there was also complete atrophy of the left Gasserian ganglion.

The anesthesia resulting from the disease of the nerve is by no means sufficient to account for the disturbance in the nutrition of the jaw; this has been proved by clinical observation and experimental research. We are constrained to assume an alteration of the trophic influence exercised by the nervous apparatus on the tissues. The trophic action of nerves has been as vehemently denied as it has been asserted in the discussions on the pathology of certain other lesions observed in the course of tabes;[4] it is the failure to corroborate the theory of such action by experimental methods that has prevented its general acceptance as an explanation of occurrences like this disease of the jaw. The recent labors of Gaule[1] have, however, shown how subtle are the conditions that determine the success or failure of experimental investigations on the trophic properties of the nervous system; it is to be hoped that the further prosecution of these researches may result in elucidating by experiment the effects wrought in cases like this by disease.

INVESTIGATIONS CONCERNING THE ETIOLOGY OF SMALLPOX.

BY J. CHRISTIAN BAY, M.D.,
OF DES MOINES, IOWA,
BACTERIOLOGIST IOWA STATE BOARD OF HEALTH.

THE question of the etiology of smallpox is one of the most interesting topics in bacteriology, and has been the subject of a considerable number of investigations during the last thirty years. A brief historic sketch illustrating what has hitherto been done in this line should, naturally, precede the record of my own investigations. The complete history of the question will be embodied in my final report to the Iowa State Board of Health, under whose authority my work[2] was carried on during the course of this year.

Numerous writers have investigated the lymph both of smallpox and vaccinia, and some have found specific micro-organisms, both animal and vegetable, which they have regarded as the primary cause of the disease or of the specific eruptions.

One of the micro-organisms heretofore more or less generally recognized as the effective agent is the *micrococcus vaccinæ* and *variolæ*;[3] Bareggi has stated that the micro-organisms of smallpox and those of vaccinia are identical.[4]

In 1868 Chauveau[5] proved that vaccine-virus is deprived of its active constituents by filtration. Hence, it became very probable that the contagion was a living organism. "For when he carefully poured a stratum of water upon a layer of lymph in tiny tubes he obtained a diffusion of the dissolved material into the water; but this clear solution could not produce pustules like the insoluble residue."

In the same year Hallier[6] described micrococci obtained from human smallpox and cow-pox eruptions.

Luginbuehl[1] discovered, in sections cleared with acetic acid, micrococci that formed colonies at certain places in the skin, near the epidermis, in smallpox eruptions.

Beale[2] found in smallpox-lymph "vast multitudes of minute particles of living matter or bioplasm," but he did not consider these the *causa morbi*.

Cohn[3] showed the presence of numerous cocci in vaccinia- and smallpox-lymph, and named them *microsphæria*, or (later) *micrococcus vaccinæ*. The organisms were quite distinct, and Cohn demonstrated their specific nature, and contended that they did not represent a stage in the development of some other organism.[4]

Weigert[5] found micrococci in the pustules of smallpox when the disease was not too far advanced and also in the blood-vessels of certain internal organs in which eruptions may be observed.

Klein[6] observed that in sheep-pox the lymphatics are filled with micrococci.

Klebs[7] has made statements that the organisms (micrococci) in vaccinia-lymph and variola-lymph exhibit peculiar physiologic and morphologic peculiarities (being about $0.5\ \mu$ in diameter), and that they must belong to the cocci which, onthogenetically, assume no other shape. In accordance with their peculiar arrangement (being grouped in fours), they were named *micrococcus quadrigesimus*.

In 1885 Voigt[8] examined the vesicles of vaccinia, and found three species of micrococci, two cocci, and a diplococcus, and in the same year L. Pfeiffer[9] published his first communication upon smallpox. The latter found in the characteristic eruptions a sprouting fungus (*Saccharomyces*) and certain saprophytic bacteria, but none of these occurred constantly. I might add in this place that the sprouting fungus that was described as a *Saccharomyces* does not belong to this genus,[10] but to the group *Torula*, in the sense of Pasteur and Hansen.[11] In vaccinia-lymph I have occasionally found a *Torula* that corresponds to Hansen's fifth species. The cells observed by Pfeiffer did not bear spores; they have no causal relation to smallpox. This *Torula,* certain saprophytic bacteria, and the animalculæ that Pfeiffer five years later reported[1] from the pustules, will appear in many other eruptions, and will not be treated of on this occasion.

It appears that some of Pfeiffer's drawings, as well as Beale's "bioplasts," indicate serious misinterpretation of the microscopic pictures.

L. Voigt[2] described, in 1885, three different forms of cocci from smallpox pustules. All liquefied gelatin, and Voigt considered one of them the probable carrier of the contagion. No definite results were, however, obtained.

In 1882, Pohl Pincus[3] proved that specific micrococci pass through the epidermis of the calf when the latter is inoculated therewith.

Hlava[4] considered the united attack by different pyogenic cocci the cause of the disease and eruptions, while Koch and Feiler were of the opinion that, although some of the saprophytic microorganisms in vaccine-lymph are pathogenic, they do not carry the contagion.

Crookshank[5] found in vaccine-lymph a great number of common saprophytic bacteria, but no specific organism.

Copeman[6] also published investigations, but found no specific carrier of the virus.

Rille,[7] in 1889, observed cocci in the vesicles and blood of persons suffering from varicella, but was unable to cultivate them.

It is very probable that Sternberg[8] was right in stating, in his text-book, that the etiology of smallpox still remains undetermined. Still, some of the investigations cited furnish very interesting points that will be valuable to those who wish to go over the field again.

Micrococci of different shape and character are, however, not the only bacteria that have been observed in smallpox and vaccinia. A few statements point toward the presence of other bacteria, namely, bacilli. Crookshank (loc. cit., 1892) mentions that he found in vaccine-lymph *bacillus pyocyaneus, bac. subtilis,* different bacterial forms, and a bacillus resembling *bac. subtilis.*

Dr. S. C. Martin[9] has described a bacillus of vaccine-lymph, the ends of which are rounded or square, and which may form micrococci (?) arranged in chains of five or six cells. He admits the possibility that both a bacillus and a micrococcus are present.

Coze, Feltz, and Baudoin[1] have discovered bacilli in the blood of variola. Upon injection of such blood into the veins of a rabbit typical symptoms of variola were produced.

In sheep-pox-lymph examined by Zimmermann,[2] three bacilli were found, one of which was very much like the *bac. amylobacter* van Tieghen. A second preparation contained a short-limbed bacillus; both showed large numbers of the *micrococcus vaccinæ* (or *variolæ*). All of Plaut's plates demonstrate bacilli which he was able to cultivate.

Toussaint's bacilli are mentioned in the dissertation by Plaut already referred to.

In April last vaccine-points were procured from Dr. Hewitt's vaccine-station, at Red Wing, Minn. A watery solution of the lymph adhering to the point contained, when examined by a magnification of 1160 diameters (Bausch & Lomb, Oc. C2, obj. $\frac{1}{12}$ oil-immersion), a few amorphous bodies, which assumed a yellowish color with iodin-potassium, iodid, and a few round bodies and irregular masses (probably nuclei or fragments of cells) dispersed in a clear, slightly-opaque fluid. I could distinguish among these bodies no micrococci or other bacteria, and no staining revealed any living organism. Some of the round bodies occasionally found (*i. e.,* in every second or third field of the microscope) may have been bacteria, but their nature was not revealed by the microscope.

A series of plate-cultures upon Pasteur gelatin[3] (10 parts of gelatin to 90 parts of Pasteur's fluid) was then arranged, but there occurred no development. Then test-tube cultures were made in Pasteur's fluid alone, and in beef-bouillon (one pound of meat to one liter of water) rendered alkaline with sodium chlorid. The vaccine-points were grasped with forceps, passed through a flame, and dropped into the fluid, which had been previously submitted to fractional sterilization, as in the usual preparation of culture-media. Great care was exercised, in order that no infection from without should take place.

On exposure to a temperature of 24° C. (75.2° F.) the culture-fluid would, on the first day after inoculation, become slightly turbid; on the second day the turbidity was increased, a thin film being formed upon the surface; and on the third day a grayish, highly-tenacious film made its appearance. Microscopic examination demonstrated the presence of colorless, non-motile bacilli, with a long diameter measuring from $0.6\,\mu$–$1\,\mu$, and the short diameter from $0.2\,\mu$–$0.3\,\mu$. During the first and second days they seemed to develop in separate colonies of from twenty to two hundred organisms each, although under the microscope many organisms appeared to be free and isolated. Macroscopically, the zooglea had, to a great extent, the same appearance as the film-vegetation of the yeast like genus *mycoderma*, being folded and of a greasy aspect. On the fourth day fragments of the zooglea begin to descend to the bottom, and the macroscopic appearance of the culture remained, after this, unaltered for three weeks and more. During this period, however, the microscopic appearance of the bacilli became greatly modified.

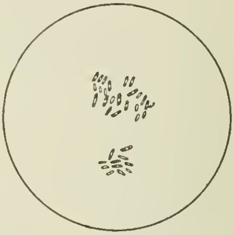

FIG. 4.

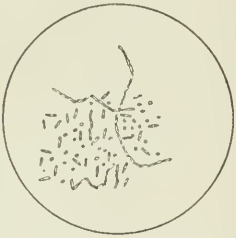

FIG. 5.

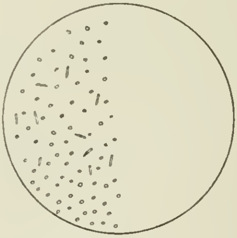

EXPLANATION OF FIGURES.—All of the figures are drawn from the pictures rendered by Bausch & Lomb, Oc. C2, obj. $\frac{1}{12}$ oil-immersion.

Fig. 1. *Dispora variolæ* growth in Pasteur's fluid, two days old.

Fig. 2. Same, four days old. Cells from surface-film.

Fig. 3. Same, eight days old. Growth in bouillon, spores being frequent.

Fig. 4. Same, twenty-five days' culture in bouillon.

Fig. 5. Same, thirty-five days' old culture in bouillon. Cells very scarce, free spores predominating.

This organism was found, with three exceptions, in examinations of sixty-five cultures from vaccine-points. Buttersack, whose recent investigations will be mentioned at the close of this paper, ventures the supposition that the specific organism of vaccinia and variola has not hitherto been detected because of its index of refraction being identical with that of the medium. I saw no reason for this supposition, and I am prepared to explain Buttersack's theory from my own observation. The bacilli that I observed have very much the same appearance as those found by Plaut.[1]

Already at the beginning of the development the bacilli bear spores. Each organism contains two spores, one at either end. This being the most conspicuous feature of the organism I assign it to the genus *Dispora*, established in 1882 by Kern, and name it *Dispora variolæ*. On the sixth day after inoculation free spores are found, both in the fluid and in the zooglea, but not before, although afterward, in the course of development. The spores are globular, highly refractive, and may be mistaken for what appear to me as vacuoles when a magnification of 2000 diameters is used. Still, the vacuoles are less refractive than the spores, and their form is rectangular (cubic) or slightly oval and a little irregular.

The same organism was also found in the lymph from a case of confluent smallpox kindly furnished by the Smallpox Hospital in Chicago. Of forty cultures in bouillon made from this lymph, only two failed to show the presence of the bacillus.

---

[1] Loc. cit., Beilage i–iv b, especially ii a.

When cultures, both from vaccine and from smallpox lymph, were examined on the eighth day after inoculation, the organisms appeared to be crowded together in distinct masses, each cell being surrounded by a rather thick layer of a gelatinous substance. Free spores were abundant.

As the culture grew older the organisms gradually became longer and longer, and on the fourteenth or fifteenth day the culture presented the appearance shown in Fig. 4. The organisms formed long, thin threads. Spores were abundant, both *in situ* and free. The number of cells henceforth gradually diminished, and on the thirtieth day very few were seen, the spores predominating. When traces of this last stage of the culture were transferred, with the utmost precautions, into a new medium, development promptly followed as already described.

The following method of staining gave very good results: A small drop of the culture was placed between two covers and slightly pressed between them. The covers, having been separated in the usual way, were placed, moist side upward, under a bell-glass. When some of the fluid had evaporated the clean sides of the covers were placed three times, for a period of two or three seconds, in the immediate neighborhood of a flame, with the thin film which was to be stained turned away from the flame. When completely dry the covers were placed in alcohol for two or three minutes, and again dried under a bell-glass; then they were brought to float, film-side downward, on anilin-blue or anilin-violet for twenty-four hours, washed, dried, and mounted in the usual way.

While this organism presented the appearance of a specific bacillus-form, I was not convinced thereof until I had made a fractional culture in bouillon, which resulted in time in a uniform development in ten or fifteen out of twenty flasks; the control-tubes revealed no development.

Regarding the polymorphism of this species, I can state that I have observed no such swellings at the middle or ends of the long cells in old cultures as Martin[1] noticed in the bacilli found by him, or as Hansen[2] described for the bacteria producing acetic acid.

From the figures of *micr. vaccinæ* and *variolæ* that I have seen I am inclined to believe that this organism is not specific, but that it represents merely the free spores of *Dispora variolæ* mihi. I also believe that the facts in regard to the spread of smallpox, as well as the observations already recorded, lead to the conclusion that the spores are the main source through which both variola and vaccinia are reproduced.

Buttersack[1] a short time ago published an account of certain bodies that occurred constantly in vaccine-lymph, and which may have some relation to vaccinia. He allowed lymph to dry on covers, and, having fixed the latter to the slides by mean of beeswax, he inspected the film by immersion and observed a network of fine threads, with small, refractive, round bodies. Landmann,[2] Dräer,[3] and Czaplewsky[4] interpreted Buttersack's discovery as threads of fibrin and other albuminates. I would, *à priori*, assume that Buttersack had seen the thread-stage of the organism found by me. Not having seen Buttersack's illustrations, I can, however, say nothing certain about this.

Experiments extending the knowledge of the natural history of the organism which I suppose to be the primary cause of vaccinia and variola are in progress. It is also within the range of my program to study the possibility of preparing vaccine in the laboratory.

SIX INSTANCES OF COLOR-BLIND WOMEN OCCURRING IN TWO GENERATIONS OF ONE FAMILY.

BY WENDELL REBER, M.D.,
OF POTTSVILLE, PA.;
FORMERLY CLINICAL ASSISTANT WILLS EYE HOSPITAL, PHILADELPHIA, PA., ALSO TO THE ST. AGNES HOSPITAL, PHILADELPHIA, PA.

The occurrence of congenital color-blindness among women is, according to most experienced observers, a rare thing. Soelberg-Wells[5] holds that "the congenital form is frequently hereditary, affecting several generations of the same family; that the hereditary form comes oftener from the mother's side than the father's; that the males are affected much oftener than females, though in some families only the latter were found color-blind."

Meyer[6] fixes the relative frequency in men and women at from 3 to 5 per cent. in the former to less than 1 per cent. in the latter. He states that the condition is hereditary and is transmitted on the mother's side, although she herself is not affected with it.[7]

Wolfe,[8] after quoting full comparative statistics as to the frequency of the anomaly in men, goes on

[7] This would seem to be in accordance with a similar law that obtains in a peculiar form of optic-nerve degeneration described by Leber, Habershorn, Norris, and Gould, and aptly designated by the last "Homeochronous Hereditary Optic Atrophy." (*Vide* Annals Ophth. and Otol., 1893, p. 303.) A law similar to that mentioned seems to prevail in hemophilia and also in idiopathic muscular atrophy.

[8] Text-book, 1882.

to say, "Females are generally considered to be rarely deficient in color-perception." De Schweinitz[1] remarks that color-blindness is extremely rare in women. Fuchs[2] merely points out the relative immunity of females, and remarks that this perhaps finds its explanation in the continuous education of color-perception (going on through countless generations) to which the members of the gentler sex are subjected from their early childhood.

Noyes[3] fixes the frequency in females at ½ per cent.

Fontenay[4] (Copenhagen), working in Denmark, found the condition in $\frac{2}{5}$ per cent. among 3819 women, and Jeffries,[5] of Boston, in 13,458 carefully-conducted examinations on females in the schools of Boston, found but 0.006 per cent. of this number presenting subnormal color-perception.

In view, therefore, of the infrequent appearance of this anomaly, it is thought that the following history may be of interest, and deserves recording:

Mrs. S., about fifty years of age, a physician's wife, complained of asthenopic symptoms that had recently been sufficiently annoying to induce her to seek counsel. Vision in both eyes was slightly below the normal. The right eye presented a small degree of hyperopia, and the left eye a moderate degree of hyperopic astigmatism (simple), which when corrected, gives her normal visual acuity. With the addition of sph. 2.00 D. for the near point, she reads type 0.50 D. from 10 to 17 inches.

Ophthalmoscopic examination without a mydriatic shows both nerves a trifle pallid, each presenting a deep eccentric physiologic excavation, and being shallowly cupped to the temporal side. The scleral ring was broad and well-marked to the outer side. The vessels were normal.

During the examination Mrs. S. volunteered the information that for as long as she could remember her color-sense had been defective. She stated further that two of her sons were similarly affected, and my pleasure at meeting a color-blind female was greatly enhanced when the patient announced that two of her sisters had the same peculiarity.

Qualitative investigation of the color-sense with Oliver's series of wools revealed complete confusion of the dark-green, dark-red, and brown. The lighter shades were better distinguished. Rose and blue were in like manner confounded. The conditions just noted were found exactly reproduced in her youngest son's eyes.

At my request, the patient furnished me with a fairly full account of the family ramifications, extending through four generations, and designating the affected individuals. It was then learned that all of the patient's sisters (numbering three) exhibited impaired color-perception, and that her only brother also possessed the defect. Thus, in this one branch of the family, all are the subjects of subnormal color-perception. The explanation of the involvement of this whole family is to be found in the history of their antecedents.

Their father was one of a similarly-afflicted family. Both his brothers and his three sisters were color-blind, a most rare occurrence.[1] Moreover, their father married a woman who, though possessed of normal color-sense,[2] had an only brother who was entirely color-blind.

Unfortunately, the history could not be traced back to the patient's paternal grandparents. She says that the grandparents on her mother's side were not color-blind as far as she had been able to gather the facts.

As to the patient's children, two of her three sons are affected, while her daughter is immune. It is worthy of remark that one of the affected sons is a twin-brother to the one who is free from the defect.

In reviewing this genealogy the following interesting features are found:

1. The involvement of two entire families in color-blindness.

2. The occurrence, within two generations, of six cases of subnormal color-perception in females.

The unusual prevalence of this affection in the family of the patient's father can only be theoretically accounted for. No facts concerning the parents have as yet been obtained. It is reasonable to assume, however, that one or perhaps both of the paternal grandparents were deficient in color-perception.

In the matter of the family of which our patient is a member, the evidence is positive and clear on her father's side, and circumstantially strong on that of her mother. Her father was a member of the before-mentioned afflicted family. Her mother, though possessed of normal color-sense, had a color-blind brother, and the presumption that she was descended from color-blind stock is allowable. According to many histories of color-blind families, there is a tendency on the part of the mother, descended from color-blind stock, to impress her progeny with the defect of her antecedents, and in the case of our patient's mother this influence must necessarily have been greatly intensified by the congenital color-blindness of her husband. I think that in this way the participation of all the children in the hereditary impression can be explained.

The appearance of so many color-blind females is of no inconsiderable import, inasmuch as it portends deficient color-perception in the males of the rising generation of this family, as shown in two of the sons of our patient.

In reference to the different ideas concerning the

---

[1] I have not found a parallel case in the literature at my command.

[2] As far as could be ascertained from members of her family.

transmission of color-blindness, this genealogy only serves to produce confusion. It does not support the inference of Meyer[1] that "color-blindness is transmitted only on the mother's side, though she herself is not affected by it." We have in this history a color-blind female bequeathing the defect to two of her sons. The history, considered as a whole, would seem to conform more to the general statement quoted from Soelberg-Wells, that "the congenital form of color-blindness is frequently hereditary, affecting several generations of the same family; that the hereditary form comes oftener from the mother's side than the father's; that males are affected oftener than females, though in some families only the latter were found color-blind."

I appreciate the fact that this genealogic tree has not been fully developed, and that many interesting facts may be brought out by a fuller study of the family histories. If the further investigation of this subject brings forth fruit, I purpose basing a future paper on the additional facts.

ALCOHOL AND PNEUMONIA.

BY JULIUS POHLMAN, M.D.,
PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF BUFFALO, N. Y.

THE action of alcohol on the different organs of the human body has been investigated so carefully and systematically that it almost seems impossible to add anything new on the subject. Looking over the literature we find abundant evidence of careful study of the question in its bearing upon heart, brain, liver, kidneys, and the digestive tract; but, strange to say, the lungs have apparently escaped attention, although a few straggling notices hinting at the true relation between alcohol and the respiratory organs have been published at different times and in different countries. As early as 1855 Dr. B. Cohen (*Zeitschr. für klin. Medizin*, Breslau, 1855, p. 401) maintained that the abuse of alcoholic drink is a strong predisposing cause of death when the drinker is attacked by pneumonia. Out of fifty-seven such cases treated at the Breslau Hospital, twenty-four died. Another notice confirming this statement is given by Dr. William Osler in a report on pneumonia in the Pennsylvania Hospital. According to this authority, pneumonia is, as a rule, fatal if a drinker is attacked when under the influence of alcohol; if cases of chronic alcoholism are excluded, the death-rate for that disease in the Pennsylvania Hospital, 29 per cent., would be only or 10 per cent. A few reports are on record of autopsies made on children who died after drinking large quantities of strong drink, stating that the lungs were dark and congested, but no experimental evidence has been given as to the action of alcohol in the production of pathologic conditions of the lung-tissue.

In order to determine this question I made a series of experiments during the winters of 1890, 1891, 1892 and 1893, and the results are embodied in this report.

The animals used were dogs, male and female, mongrels of very mixed origin, picked up from the streets by the city dog-catchers. They ranged in weight from fifteen to twenty-five pounds, and were all apparently in good health, if voracious appetites and strong fighting propensities can be accepted as indications of physical well-being. Twelve animals were used during 1890–91, ten the following winter, and nine during the winter of 1892–93.

The experiments were simple. The animal, carefully etherized, received an injection of a quantity of commercial alcohol, varying from one dram to one ounce, into the trachea just below the larynx, by means of a large hypodermic syringe. After the narcosis had passed away the symptoms were noted, from hour to hour first, from day to day later. and post-mortem examinations made after a certain time, varying from half an hour to four weeks, gave evidence of the internal conditions of the respiratory organs.

The general symptoms were invariably the same, differing in severity only according to the quantity of alcohol given and the age, weight, and strength of the animal experimented upon. The terms age and strength are used guardedly, for the temptation is strong to say "idiosyncrasy;" otherwise it is difficult to account for the different effects produced by equal quantities of alcohol upon dogs of the same weight. For instance, two dogs, each weighing twenty-five pounds, were treated with a dose of two drams each, and one died after one hour, and the other after six hours; while two other dogs of twenty-four pounds weight, and two more weighing respectively fifteen and eighteen pounds, received the same quantity, two drams each, and all four survived and were as well as ever after four weeks. One dog, weighing eighteen pounds, died in five minutes after receiving two drams of alcohol, while another, of fifteen pounds weight, took *one ounce*, and recovered.

So, whether there is a similar idiosyncrasy in dogs as there is in men, or whether the differing results were due to age and strength of the animal, is an interesting question open to discussion.

The symptoms in all dogs experimented upon were alike and as follows: difficulty in breathing, increasing with the advance of the inflammation set up in the respiratory passages by the action of the alcohol, until it finally resembled a wheezing noise and called into activity all the accessory respiratory muscles; stethoscopic examination gave evidence not only of the difficulty which the air encountered in trying to force an entrance into the bronchial tubes and air-vesicles, but also of the tumultuous beating of the heart while attempting to drive the blood through the capillaries of the lung. Copious expectoration of a bloody, frothy mucus indicated the progress of the disease.

---

[1] Already quoted.

As the animal weakened it usually pressed itself against the wall of the room with the thorax as much as possible resting on the floor, and displayed a constant desire for cold water, probably due to the feverish condition induced by the inflammation. No temperatures were taken, for after three thermometers had been broken by the struggles of the animals the attempt to gain correct information on that point was abandoned.

Post-mortem examinations always showed the lungs dark and congested, solid in some places, so solid indeed that these parts sank when thrown into water.

Cutting into the lung, the air-passages were found to be always filled with bloody frothy mucus; even the animal that died five minutes after the injection presented the same symptoms. The lungs were dark and congested and full of bloody mucus, showing the rapidity of the inflammatory processes and clearly demonstrating how *acutely sensitive the respiratory passages are to the action of alcohol.*

There is probably no danger of meeting contradiction when we define pneumonia as an inflammation of the lung-tissue; whether of bacterial or traumatic origin, of lobar or lobular form, need not concern us here, as long as we are satisfied that these inflammatory processes produce the phenomena observed in the respiratory passages during an attack of the disease.

Alcohol introduced into the lungs of dogs sets up a pneumonia more or less severe. Whether we call it a traumatic pneumonia, or a broncho-pneumonia, or coin a new name for it, will not change the fact.

On microscopic examination of such lung-tissue the air-tubes and vesicles are found to be partially or completely filled with immense numbers of red and white blood-corpuscles and large quantities of mucus, and present the same picture as that obtained from a slide made from the lungs of a child that died from broncho-pneumonia, and although one is from a human being, the other from a dog, the former representing a well-known type of disease, the latter an artificial form, the similarity between the two is certainly striking enough to prove that the pathologic condition of the lung-tissue is the same in both, and that the alcohol has induced inflammatory processes very closely resembling, if not absolutely like, those found in attacks of broncho-pneumonia in human beings.

Admitting then that alcohol *can* produce all the grades of inflammation of the lung-tissue from the mildest to the fatal form, according to the quantity used, we can perhaps understand to some extent why drunkards if attacked by pneumonia will succumb more speedily than the patient of temperate habits.

By virtue of the alcohol coursing with the blood through the lung-capillaries on the one side, and the alcohol exhaled with the breath, be it ever so little, filling the air-vesicles and air-tubes on the other side, the lung-tissue itself, so sensitive to alcohol, stands between two fires, so to speak, and must be in a chronic state of semi-engorgement, of mild inflammation, like the highly-colored nose of the drunkard or the engorged mucous membrane of his stomach.

Certainly such a state of affairs will change the normal condition of the cells of the lung-tissue and reduce their vitality, and in proportion their power of resistance to external influences; and if now a severe, acute form of inflammation, such as pneumonia, is added to the pathologic conditions already existing, the lungs find themselves powerless against the attack of the disease, and the drunkard's death-rate from pneumonia illustrates the time-honored law which says that an organ or organism weakened by previous ills cannot compete with normal organs in fighting the battles against acute diseases in the struggle for existence, and the man of temperate habits, with lungs free from alcoholic inflammation, has from five to seven chances for recovery from pneumonia when the drunkard has only one.

CLINICAL MEMORANDA.

SOME RHINOLOGIC CASES OF INTEREST.

BY WILLIAM MARTIN, M.D.,
OF BRISTOL, PA.

THE object of this paper is merely to take a few cases of interest from my case-book that are in a way unique, if not a little unusual, and present them briefly.

CASE I is one of *angioma of the naso-pharynx.*—The patient, Annie M., aged about forty years, came to my office during the summer of 1893, complaining of a decided obstruction in the nares, compelling her to breathe through the mouth, and also of a feeling of fulness in the upper part of the throat. She had noticed these symptoms for quite a long time, but considered them as due to a catarrhal trouble which she had been aware of for some years. Noticing that the symptoms were becoming more decided, and seeing an occasional discharge of bloody mucus, she considered it time to consult a physician. I could get no history of a decided epistaxis, although the oozing seemed pretty constant.

The symptoms other than these were those of an ordinary hypertrophic rhinitis which were of no diagnostic value. Upon examination I found anteriorly the nasal chambers showing evidence of a mild type of this form of rhinitis, with considerable turbinated hypertrophy toward the posterior part. Upon inspection of the post-nasal space by means of the rhinoscope, the condition of things was immediately apparent.

The object or growth may be described as follows: A fairly-large, rounded tumor, filling pretty completely the right side of the upper pharyngeal space, and of course hiding from view the opening of the Eustachian canal of that side, and extending a little beyond the median line.

The color was red, showing great vascularity. Upon close inspection the tumor was found to pulsate synchronously with the heart-beats. By gentle use of the probe the attachment was determined to be to the posterior turbinated tissue, and of a slender character, as the tumor was movable. Even with gentle manipulation it bled a little, so that I was careful not to persist in my examination. To my mind the diagnosis was quite apparent.

I informed my patient of the character of the trouble and the dangers attendant upon operation, although this has been done successfully. An appointment was made, as she seemed willing to take the risks, but from that time to this she has not come back, so I cannot tell the outcome of her trouble. To me the case was of great interest because of the rarity of occurrence of this form of tumor.

From what I can find by searching my stock of literature the most complete article on the subject is one by Seiler.[1] He mentions a list of rhinologists who have had cases in their practices, and says of them, "but a careful examination of the clinical features of all these cases as reported leaves us but ten in all which were undoubtedly angiomata, and from which number our knowledge of this rare form of intra-nasal neoplasm is derived." These refer particularly to the growth met in the nasal chambers; while this I feel assured was attached within, yet the major portion was in the post-nasal space. Later in his article Seiler refers to the importance of distinguishing this form of tumor from a true hypertrophy of the turbinated tissue, because of decided difference in the result of operative interference. The clinical distinction is in the pulsation, which is always present in true angioma; otherwise the two may appear very much alike. The other growths to differentiate between are those presenting angiomatous features, such as telangiectatic polypus or angio-sarcoma. The same pulsating condition is the distinguishing feature here also. It is recognized that operative interference is dangerous and has proved fatal, yet it is important in some cases to remove the growth. When this is done, the preferable way is by the cold-wire ècraseur, and the manipulation must be very gentle and carefully slow.

Seiler prefers to allow the excised tissue to remain *in situ*, undisturbed for from twenty-four to forty-eight hours before removal. He mentions also that partial excision is often followed by complete disappearance through post-operative shrinkage. If this description establishes my diagnosis as correct, this will add one more case to the now very small list of angiomata of the nasal cavities.

CASE II. *Foreign body in the nose.*—The interest of this case is not because of any rarity of occurrence, but from the fact that the condition of the nasal chamber simulated the atrophic form of rhinitis, and also in the fact that it was mistaken for this by another physician.

The patient, Beatrice C., a child of two-and-a-half years of age, showed evidence of a nasal obstruction, with an excessive amount of offensive discharge that seemed to increase in amount and character. This gave the impression to the parents of an ozena, and it was for this trouble that they consulted me. The condition was first noticed a year previously, the principal symptoms being apparently pain, and subsequently obstruction.

Upon being questioned, the mother recollected the child playing with shoe-buttons at about that time, but had overlooked the matter. After cleansing the naris with a warm alkaline antiseptic spray, I could feel with a probe a resisting object that gave the impression of necrosed cartilage. Upon further examination under chloroform, as this was necessary, I determined the object to be a shoe-button tightly lodged in the upper sinus, rather posteriorly, and only after bringing to bear considerable force was it dislodged. It proved to be a shoe-button apparently swollen and porous, which fact, no doubt, accounted for the sensation of necrosed cartilage given by the probe. Following the extraction there was considerable hemorrhage and flow of offensive muco-pus. The cavity was thoroughly cleansed, and a bland alkaline antiseptic spray ordered. Healing was natural, and, as far as I can learn, there have been no subsequent nasal symptoms, and the child is growing nicely and seems well. I may say before leaving this case that the child was seemingly in poor health and growing worse gradually, and, as there is a tuberculous family history, the parents became quite alarmed.

CASE III. *Deviation of the septum.*—Herbert ——, aged about twenty-six, a civil engineer, has complained for some years of entire closure of one nostril. He was told by a physician of the town in which he lived that the case was one of polypoid growth, and an operation was talked of. Before this was decided upon he was persuaded by one of his relatives to consult me about it. Upon examination the appearance was as follows: Anteriorly the right side was a large cavity with decided turbinated hypertrophy, no doubt from doing double duty in the performance of respiration. The left was no longer a cavity, being filled entirely by the decidedly deviated septum, which was united to the hypertrophied turbinated tissue, and to such an extent that a small probe could not be introduced. The septum was deflected from above downward and, as well, from the anterior to the posterior portion, making an angle that seemed from the right side very acute, but from the left less so, because of the cartilaginous thickening. The man expressed a desire to receive treatment; so a preliminary course of local applications was instituted, and these were followed by the septal operation. This was done very much after the usual manner, the first step being to make a way through the turbinated tissue with the galvano-cautery, sufficiently large to admit the septal punch and other necessary instruments.

Following the straightening of the septum, the turbinates on both sides were thoroughly cauterized, and the parts cleansed and dressed.

The only means used to hold the septum in place was a wad of cotton packed snugly, and changed sufficiently so as not to become foul. A 10 per cent. solution of cocain was all that was required for anesthesia.

---

[1] System of Diseases of Ear, Nose, and Throat, vol. ii.

At present writing, almost nine months since the operation, the septum seems strong and in proper position.

While this condition of the septum is not of infrequent occurrence, it certainly is of interest, because of its frequency, and shows that care must be exercised in the examination of the nasal cavities, not only to establish a proper diagnosis, but also to enable one to extend the proper kind of relief.

CASE IV. *Split septum.*—This patient, George A., a mechanical engineer, came to my office with a history of having been thrown forcibly from his bicycle, striking his head and face, the latter receiving the force of the fall, especially the nose, which soon became very much swollen, while the breathing was entirely obstructed. After about a week's suffering, being absent from home at the time of the accident, he came to my office.

Upon examination I found the condition as follows: Externally, the nose was very much swollen, and internally, both the cavities were occluded. Examining more carefully, the occlusion was found to be due to a separation of the two plates of the cartilaginous septum with an exudate filling the intervening space, and giving the whole the appearance of bagging. The probe would produce fluctuation, and by some force the plates could be partially approximated. The turbinates were normal, so that there was no doubt about the diagnosis.

The treatment consisted in pressure over the parts, to approximate the plates, and local remedies to allay the inflammation and to promote absorption of the exudate. These were employed daily for a couple of weeks, and then occasionally. The exudate was absorbed, and no doubt union between the plates must have taken place, for when the treatment was discontinued the septum seemed almost normal, except for a slight thickening, which may in time disappear.

This form of accident is very unusual if not rare, as a separation of the plates could only be brought about by direct force against the bridge of the nose, and even with such a force it does not always result. The literature on this subject is scant, as far as I can find. Mention is made by Seiler[1] of this condition, but it is treated very briefly. This refers only to the splitting by traumatism, as it is possible for this to happen as a pathologic condition.

CASE V. *Angio-neurotic edema.*—Emma C., aged about twenty-eight years, came to my office complaining of an ordinary hypertrophic rhinitis, for which she was treated in the usual manner. The catarrhal inflammation was gradually improving, and everything seemed satisfactory, when one morning, to her alarm, she noticed a puffing of the tissue under the left eye. This swelling extended rapidly, and in a short time the whole side of the face was swollen, closing the eye tightly. There were no subjective symptoms other than a feeling of tightness and awkwardness of the parts, with a slight burning sensation. Of course, vision in the one eye was suspended temporarily, which annoyed her very much. She could not account for her condition in any other way than, as she expressed it, "the catarrh has gone to my eye." The condition was recognized and an explanation attempted, but owing to ignorance on her part, combined with a nature rather of a melancholy character, the impression could not be dislodged from her mind, and fearing that the swelling might be driven to other parts she discontinued the treatment; so I lost sight of the case, although not until the swelling had subsided, which was in about five days. The only treatment for this condition consisted of frequent applications of hot water to the swollen parts.

While this case does not strictly come under the heading of this paper, it is connected with the subject, inasmuch as it occurred in one of the patients under treatment for a nasal condition, and was probably due to some excitation of the nasal nerve-terminals in a neurotic patient, from the use of the applicator. It certainly is of interest in a general way, as the present knowledge of this condition is not excessive and the number of cases reported is not large, while the condition is not a rare one. Probably the time will come when we shall understand the subject more thoroughly, and until that time each case reported must be of some interest.

SOME ADDITIONAL EXPERIENCES WITH BEHRING'S DIPHTHERIA-ANTITOXIN AND SOME REMARKS ON THE USE OF LOEFFLER'S TOLUOL-SOLUTION.

BY EDWIN J. KUH, M.D.,
OF CHICAGO, ILL.

IN the *Journal of the American Medical Association* of December 1, 1894, I published the following brief report of a seemingly promising case of laryngeal diphtheria that terminated fatally, however, in spite of the reasonably prompt injection of the antitoxin:

Freda H., a robust girl, aged seven years, complained of hoarseness on November 6th, and remained indoors without symptoms of fever until November 11th. On that day she took to her bed, and Dr. F. W. Mercer saw her for the first time. On the same afternoon I saw her in consultation with Dr. Mercer. During the the day the temperature had ranged at slightly over 102°. The fauces *were entirely normal*, with the exception of a small, white, loose deposit on both tonsils, which was easily brushed away with cotton mounted on a probe. The child was hoarse, and the larynx somewhat stenotic. There was no retraction of the chest upon inspiration. Bronchitis existed in the larger tubes. Examination of the larynx was very unsatisfactory, because of an unusually depressed epiglottis and the child's intolerance of laryngoscopic examination.

The next morning, November 12th, the child coughed up a piece of membrane two inches in length, one-half an inch in width, and one millimeter in thickness. Laryngeal respiration was but slightly improved, and shortly after became very difficult. The temperature was about as before, but the pulse-rate became as high as 165. I saw her the same afternoon with Dr. Mercer, and injected ten cubic centimeters of Behring's antitoxin No. 2. A few hours afterward Dr. W. K. Jaques performed intubation. Cultures taken from the larynx showed the presence of Loeffler's bacilli.

On the morning of November 13th the temperature reached 104.5°, the pulse-rate was not lower, and the lungs were filled with fine crepitant râles.

This rapid inception of broncho-pneumonia led to a fatal issue at midnight of the same day. We could not observe that the injection of the antitoxin had made any impression whatsoever on the pulse or temperature of the child.

---

[1] System of Diseases of the Ear, Nose, and Throat, vol. ii.

This unfortunate case must, however, not be considered as evidence against the efficacy of Behring's remedy, as the result was evidently clouded by the complication. The child did not die of diphtheria but of broncho-pneumonia.

Since then my experience with the remedy has been more favorable.

Eleanor B., aged five years, daughter of Dr. B., was visited December 10th by a cousin who had had diphtheria, but from whose throat the membrane had disappeared eighteen days previously, and cultures from whose throat had finally been pronounced free from Loeffler's bacilli. On December 16th the child, who was visiting relatives in the suburbs with her brother, aged eighteen months, became ill with diphtheria. She was brought to the city the following day, and was seen by me in consultation with Dr. W. S. Christopher. We found moderate swelling of the submaxillary lymph-glands, patches on both tonsils and on both sides of the posterior pharyngeal wall extending upward toward the post-nasal space. The systemic infection was slight, and the temperature-maximum did not exceed 102°. Cultures gave an almost pure growth of Loeffler's bacilli. I injected 600 antitoxin normal units on the 17th. The membranes began to exfoliate on the following day, and disappeared entirely within forty-eight hours after the injection. Pulse and temperature became normal on the 18th. Ten days after the injection the child developed an extensive erythema. During the short course of the disease it was deemed expedient (with all due apologies to Prof. Behring) to treat the throat locally with Loeffler's toluol-solution.

Three days after my first visit Mrs. B., the child's mother, complained of excessive prostration and some tenderness in the throat. The right tonsil, concealed in the palatal folds, was found covered with false membrane, from which a fragment was easily removed. From this piece of membrane I received the most exquisite pure culture of Loeffler's bacilli I have ever grown from the throat. An application of Loeffler's solution was immediately thoroughly made to the surface of the diphtheric tonsil, and within a few hours the temperature declined from 99.5° to normal. On the following day the temperature rose to a maximum of 100.4°, and more membranous patches were seen farther to the left on the posterior pharyngeal wall. They were treated every three hours with applications of toluol, and the antitoxin was reserved for an aggravation of the disease, which, however, did not occur, as within forty-eight hours the patches disappeared entirely.

December 21st the younger child of Dr. B., aged eighteen months, developed a temperature of 101°. The child had been kept with the relatives (already mentioned) in the suburbs for purposes of isolation, but was now brought to the city because it was feared that he also was developing diphtheria. The appearance of the throat on the 21st certainly gave the most cogent reasons for that belief; for though no membrane had yet formed we were prepared to find it there the following morning. Unfortunately, no cultures could be obtained from the child's throat, because he had a knack of filling his mouth and throat with saliva in order to ward off attempts at examination. He received a preventive injection of the antitoxin, after which on the following day all malaise, from which the child had been suffering on and off for a week, disappeared. In this connection it might be mentioned that in the family in which the children lived before being transferred to the city a child, aged fourteen years, developed diphtheria on December 24th, probably traceable to contact with Dr. B.'s children.

Ursula S., aged fourteen years, was seen December 19th through the courtesy of Dr. J. W. Dal. She, as well as the numerous other children of the family, had been suffering from hoarseness for about a week. Her condition on the 19th of December was such as we see in laryngeal diphtheria. Both tonsils were covered with patches which had not yet become confluent, and on each side of the pharyngeal wall a membranous deposit extended downward. The child was quite croupy, and the laryngeal affection such as to suggest the probable necessity of intubation within twenty-four hours. The culture-tube and the microscope confirmed the diagnosis of Loeffler's diphtheria. In this case there was a preponderance of other micro-organisms in the culture, among which a capsule-diplococcus was conspicuous. I injected 1000 antitoxin normal units and Dr. Dal kindly made regular applications of toluol to the tonsils and pharynx. The membrane loosened within the next twenty-four hours, and the constitutional symptoms, which had not been severe, promptly improved. Two days after the injection the patches had almost disappeared, although the hoarseness still persisted to some extent. Toluol was then gradually discontinued and a spray of corrosive sublimate substituted. On the afternoon of December 24th the child suddenly became worse, and on Christmas day there were again two deposits on the pharynx, with a return of the threatening laryngeal symptoms and considerable involvement of the submaxillary glands. I again injected the antitoxin (10 cubic centimeters of Behring's No. 1 solution), with equally prompt response. The child continued to improve, and further recovery was uneventful with the exception of an urticaria-rash, which subsided in a couple of days.

Sydney R., aged thirteen years, spent a week in a house at Terre Haute, Indiana, in which diphtheria had occurred six months previously. He returned to Chicago December 31st, complaining of pain in the throat and general lassitude. I saw him the same night, and found a suspicious patch on the right tonsil, which I brushed thoroughly with Loeffler's toluol-alcohol-iron solution. The next morning the membranous deposit extended over most of the pharyngeal wall and to the left tonsil. The membrane on the right tonsil, to which toluol had been applied the previous night, had mostly disappeared. I injected nine cubic centimeters of Behring's antitoxin No. 1, and ordered the toluol-applications to be continued. Within the next twelve hours there was a continuous increase of the exudate, with extension slightly above the palatal arch; the temperature was 102.5°, the pulse 120, and there was intense somnolence. At that time the impression of the case was such as under ordinary circumstances would have offered a very grave prognosis. On the morning of January 2d, however, two-thirds of the membrane had come away; the temperature was elevated but slightly above normal, and the boy was bright and cheerful. On January 6th all traces of pseudomembrane had disappeared. In this case the diagnosis of Loeffler's diphtheria was verified in the usual way. The boy's mother, who had been seriously exposed before I saw him, had a rise of temperature on January 2d, due to an inflamed throat, but, possibly owing to applications of toluol, did not contract the disease.

It seems to me rather important to mention that after the application of Loeffler's toluol-solution, scattered, filmy, and somewhat tenacious grayish deposits appear in the throat, which are not diphtheric, but due to some chemic action of toluol on the secretions and epithelium of the throat. It is necessary to guard against the error of interpreting these chemic deposits as new invasions of the disease.

Toluol seems to me destined to become a very important auxiliary treatment in conjunction with the antitoxin in the mixed infections of diphtheria. In the pseudodiphtheria of scarlet fever it will probably be classed as a supreme local remedy. Unfortunately its pungent qualities will exclude it from application in nasal and pharyngeal invasion of the disease. The early diagnosis and treatment which the future will exact from every conscientious physician will naturally be a safeguard against infections beyond the reach of a combination of antitoxin and toluol.

There has until now been no local abortive treatment of acute follicular tonsillitis, the claims made for guaiacol to the contrary notwithstanding. Loeffler's toluol-solution has aborted all of the cases of acute follicular tonsillitis within my notice during the past weeks, two or three of these being particularly severe.

The introduction of this remedy will naturally lose in éclat by being overshadowed by the antitoxin. It is fortunate that we have become so suddenly doubly enriched; for after the smoke has cleared away we shall, I believe, realize that not every case of diphtheria should be treated with injections of the antitoxin, which are not so harmless as they were at first supposed to be. Each of the two remedies will find its sphere, and frequently they will be used in combination.

I am indebted to my brother, Dr. Sydney Kuh, for his kind assistance in establishing the microscopic diagnosis in these cases.

A CASE OF ENTERIC FEVER OCCURRING IN ADVANCED PREGNANCY.

SERVICE OF S. S. STRYHER, M.D.,
PRESBYTERIAN HOSPITAL, PHILADELPHIA.

[Reported by P. M. ASHBURN, M.D., Resident Physician.]

THE following case is interesting as showing the course of typhoid fever during pregnancy, some of the difficulties that may attend its treatment, and the usual result.

The patient was a young white woman, twenty-two years of age, who was married and had had one child, which is living and healthy. Her family history is good, and she had never been sick before. She was brought to the hospital after two weeks' illness, with fever, diarrhea, and cough, from one of a row of houses from which we had removed another patient with the same disease about two weeks previously. All the people in this row obtained their drinking-water from a common well, and all the houses had privy-vaults close at hand.

The patient was admitted August 6, 1894, and I will first quote the notes made at the bedside during her sickness.

On admission the patient complained of fever, cough, and diarrhea, and said she was about seven-and-a-half months pregnant. Her temperature was 104.2°, the pulse 152, the respiration 52. She was of medium size, and weighed about 125 pounds. The skin and mucous membranes were of good color, the cheeks flushed, the pupils normal and reacting to light and distance. The tongue was dry and coated with a brownish-white crust. The pulse was rapid, rather weak, of low tension, and somewhat dicrotic.

The chest was well formed, the lower part wide from abdominal distention. The respiratory sounds were harsh, especially posteriorly. Examination of the lungs was otherwise negative. The heart-sounds were rapid but of good strength.

Hepatic dulness extended from the sixth rib to the costal margin; splenic dulness from the eighth to the tenth rib. The abdomen was large and bulged symmetrically; the linea albicantes were abundant. There was dulness on percussion in the umbilical and hypogastric regions, but elsewhere the note was clear. The uterus could be outlined, with its fundus at about the level of the umbilicus. Fetal movements could be felt. Fetal heart-sounds were heard in the right lower segment, the placental souffle on the left. The patient was being tubbed, and required from two to four baths daily. Her great complaint was of cough.

On August 11th the patient had at various times complained of severe abdominal pain, feeling like uterine cramp. It was on this evening severe while the patient was in the tub. On August 12th a systolic murmur was heard at the base and apex of the heart. On August 14th the patient had had twenty-one tub-baths. The temperature generally fell to 100° after a tub. The pulse became very rapid and feeble; after a tub the night before it was 204. Tubs were not now required as frequently as a few days previously. The patient vomited her medicine and milk, the vomiting being excited by cough. She still complained of cramps in the abdomen. She had been delirious at times. The face was now clearer than a few days before. The tongue was still coated and there were sordes on the teeth. The respiratory sounds were harsh and abundant dry râles were heard. The heart-sounds were rapid, and a systolic murmur was present at the apex. The abdomen was larger than at the time of the previous note. No rose-spots had been seen.

On August 20th the woman had been doing fairly well, the pulse and respiration being stronger and less rapid. The patient had complained a good deal of abdominal pains, but they were in a measure controlled by morphin. On the previous morning she had complained of greater pain, and at 9.10 A.M. her child was rapidly born. There was no tear and little bleeding. The placenta came away without trouble. The child lived for about half an hour. It was a male and measured 37.4 cm. in length and weighed 1030 grams. Its nails were well developed. The placenta was rather small and came away intact. Into one side of it there had been a hemorrhage, involving a strip about one inch wide by five inches long.

The patient's temperature remained high after the labor, and she was sponged several times with apparently little effect. The night before the temperature still continued high, and she was tubbed for twenty minutes, after which the temperature fell to 99°. The temperature continued to fall slightly until morning, and at 9.30 A.M. was 95.4°. The patient perspired profusely at 4 A.M. There was now no pain in the abdomen. The pulse was somewhat rapid but of good strength and volume. The tongue was dry. The heart-sounds were fairly strong; there was systolic roughening. The abdomen was moderately distended and tympanitic all over. The lochial discharge was very slight. The patient complained of the feet being painful and tender; the legs were slightly tender; the feet were white and very slightly swollen; the slightest pressure on them caused pain.

On August 23d, over the upper portion of the back and on the right shoulder was noticed a thick-set eruption of small, salmon-colored papules, many of them surmounted by very small vesicles. The eruption itched, but was now fading. After the last note the temperature remained subnormal, at one time being 94° by the mouth and not registering in the axilla. The tongue was dry, cracked, denuded in patches. The breath-sounds were slightly blowing at the right apex anteriorly, elsewhere somewhat harsh. There was roughening of the systole over the base and apex. The abdomen was only moderately distended, tympanitic, and tender in the epigastrium. The pain in the toes and feet had almost disappeared.

September 6th, the temperature had been normal since the last note. The patient was now being propped up in bed daily. The facial expression was good, the tongue clean and moist, the pulse accelerated but of good strength and volume, the heart-sounds clear and soft, the abdomen not distended or painful, and there was no vaginal discharge. The rash on the back and shoulders was desquamating and fading.

From this time on the patient had no trouble, and was finally discharged cured.

The treatment of this case was largely symptomatic. The ever-present uterine pains warned against too greatly shocking the patient by cold baths, while the high temperature, at almost all times above 104° in the axilla, being uninfluenced by sponging and small doses of antipyretics, necessitated something of the kind. She was therefore tubbed when the temperature reached 103°, being placed in water at 80°, and that gradually reduced to 70°, and kept there for from twenty to thirty minutes. The temperature would thus be reduced to about 100°. The rapid and weak pulse and respiration, occasionally rising to 200 and 55 respectively, and nearly constantly remaining at from 140 to 190 and 36 to 50, called for stimulation, while the fear of their action on the uterus forbade strychnin and kindred preparations, and whiskey, which was vomited as soon as taken by the mouth, could not be much used by enema. That element was finally partially controlled by the hypodermic use of digitalis and morphin in small doses and small and frequent dosage of champagne by the mouth. The irritability and crowding of the stomach also made it impossible for any food but very small quantities of peptonized milk to be retained, and that was very often rejected.

Finally, when it was hoped that the temperature might soon subside, it prevailed against the treatment, and hemorrhage into the placenta, with miscarriage, resulted.

Then followed another peculiar feature, in the subsidence of the fever by crisis twenty-four hours after the miscarriage, and its continuance for four days between 94° and 98°, by the mouth, and then gradually rising to normal.

The skin-eruption was also not uninteresting. The systolic roughening was interesting if not unusual. The urine contained albumin in small amount for a time, and thus caused slight anxiety, but no symptoms of eclampsia were manifested.

AN EXPLOSION OF TUBERCULOSIS, WITH A PECULIAR TUBERCULOUS LYMPHANGITIS, IN A BOY FIVE YEARS OLD.

BY BAYARD HOLMES, B.S., M.D.,
PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS OF CHICAGO.

IN January, 1888, a boy five-and-a-half years old was brought to me by a gentleman seventy-two years of age and a lady about fifty. I supposed that he was a grandchild, but was assured that I had before me the little fellow's father and mother. They gave me the following history. In the preceding June the boy had fallen upon a wood-pile and injured his left knee. During the succeeding month or two he had complained of lameness, which was then followed by a slight swelling over the left patella. Two months later numerous "swellings" appeared in various parts of the body. One of these swellings broke and discharged a thin pus at the outer border of the left gluteus maximus. The swelling over the patella opened a little later. The boy had run down all the time. Upon examination I found nine unopened tumors and two discharging tuberculous sinuses. There was an evident tuberculous inflammation of the sheath of the extensor tendons of the left toes; there was evident tuberculous disease between the astragalus and calcaneum of the right foot; there was a large superficial tuberculous lymphangitis in the left calf, and two similar accumulations upon the internal and upon the external border of the left quadriceps extensor femoris. There was one similar accumulation, about eight inches long, which seemed to be within the sheath of the semi-membranosus of the right leg. There was a large liquefied tuberculous adenitis in the right axilla, and there was a small tuberculous lymphangitis along the border of the right biceps. Each of these tumors was long and indistinctly fluctuating. The two open tumors were discharging pus, which was certainly tuberculous, and their exposed surfaces were covered with tuberculous granulations.

After proper preparation an operation was undertaken. The astragalo-calcaneal joint was first carefully opened and curetted. The extensor tendons of the left foot were then exposed and their sheaths trimmed out with scissors. These wounds were closed. The lymph-space abscesses were then carefully opened, trimmed out, and packed with iodoform-gauze. Last of all, the open abscesses were cleaned and curetted and treated by the open method of iodoform-gauze dressings. The operation required a little more than half an hour, and the patient recovered from the anesthetic promptly. During the following two months the larger abscesses were scraped out three times, and all of them closed except four. Two new abscesses appeared in the neighborhood of the old ones, and these were opened and curetted. The patient lost strength very much during the first six weeks after the primary operation, and the weakness was exhibited by a curvature of the spine, which for some time promised tuberculous disease of the vertebræ. Nothing of this kind, however, occurred; and by good feeding and careful nursing the patient was completely restored. All the wounds were healed within six months after the primary operation. The patient is now (1894) a strong healthy boy, over-sized rather than under-sized, with no appearance of a return of the disease. The family has been warned that at between fourteen and eighteen years of age another explosion may be expected. The peritoneal cavities of two guinea-pigs were opened and a gram or two of the granulations from an unopened abscess were introduced on the sharp spoon. These guinea-pigs were examined after death and showed, one a large tuberculous peritoneal abscess with general tuberculosis, and the other a general miliary tuberculosis. The first was killed five weeks and the second seven weeks after inoculation.

In investigating the origin of this tuberculosis, examination was made of the cows from which the boy had been fed during the previous two years. This herd consisted of three "scrub" cows, with not the slightest sign of tuberculous disease. The udders were free from any lumps, nor could any history of sickness in the herd be obtained. The household was carefully examined, and not the slightest trace either of hereditary or acquired tuberculosis in any member of the family or in any servant could be elicited. Among the visitors, only one could be distrusted. This was a little girl, twelve years old, that had suffered a year before from scarlet fever, followed by suppurative disease of the middle ear. The ear was said to have been discharging during a six weeks' visit to the house, which occurred the spring previous to the onset of the disease in the little boy.

A year-and-a-half after the boy had entirely recovered the father consulted me in regard to an acute orchitis in the right testicle. This gave me a history that I had not heard before. Fifteen years before he had had an orchitis that came on rather slowly, never being particularly acute, and resulting in a round, spongy tumor at the side of the testicle. This tumor was punctured several times by the physicians who attended him, without the removal of anything except a little blood and a show of cheesy matter. For a year-and-a-half after the first appearance of the disease, the tumor remained the same size, giving rise to little pain but to much uneasiness. No exact diagnosis was given at the time, although the most prominent surgeons in Chicago were consulted. At last the tumor nearly disappeared, but remained as a hard lump at the lower end and inner side of the testicle. Upon various occasions it showed a disposition to enlarge and become slightly painful. When examined by me the right testicle was found distinctly atrophied, being hardly two-thirds the diameter of the left testicle. The head of the epididymis was as large as a walnut; it was hard and firm, except in one small place, where it appeared to fluctuate. A hypodermic needle was introduced into this fluctuating portion, and a fine granular pus was removed, which upon microscopic examination proved to be distinctly tuberculous. This small abscess was treated with iodin and iodoform injections, with repeated aspiration of the pus. A moderate degree of reaction followed, and subsequently the tumor returned to its dormant condition. The father died suddenly in his chair a year after this treatment. He was then seventy-four years old, and an otherwise apparently strong and healthy man.

A CASE OF TRIPLE MAJOR INJURIES.

Service of W. S. HUSELTON, M.D.,
SURGEON TO THE ALLEGHENY GENERAL HOSPITAL.

[Reported by Joseph C. Ohail, A.M., M.D., Resident Physician.]

On April 19, 1894, Phillip B., aged sixteen, employed in an iron-factory, was brought to the Allegheny General Hospital, suffering from a fracture of the left femur at its middle third, a fracture of the right leg near to and probably involving the knee-joint, and a terribly lacerated and broken left arm. From the middle of the forearm down nothing remained. The humerus was broken in several places, the seat of the upper fracture being at the junction of the upper and middle thirds. The upper fragment was projecting, and the skin and fascia were completely torn off up to the shoulder, presenting an appearance like that of a coat with its sleeve torn out. The man had been standing on a platform which ran along just beneath a hanging shaft, when in some way a belt which had been broken became wrapped around his arm. On the belt tightening he was caught and revolved about the shafting, which was eighteen inches from the ceiling. His legs were broken by striking the ceiling. He was released only when his forearm gave way.

The brachial artery could be seen pulsating along the greater part of its course. There was but little hemorrhage. The axillary artery was first ligated just below the subscapular. One end of the ligature was left to project beyond the line of the suture. The humerus was then disarticulated, and as much as possible of the muscular tissue about the shoulder was removed, so that the skin might cover the wound. Even after doing this there was much tension on some of the sutures. It is to be remembered that not a particle of skin was cut away.

The right leg was put on a double-inclined plane, and extension was applied to the left leg.

For the first three weeks the temperature ranged between 99° and 100°. The highest during the history was 100.8°.

The left leg was kept in extension for thirty-seven days. Union was complete. The right leg was kept on the double-inclined plane for fifteen days, then twelve days in an ordinary fracture-box, and then fourteen days in a plaster cast. Union was good, with no deformity.

The stitches of the amputation-wound were removed on the tenth day, and the ligature on the axillary artery came away. The wound had healed nicely save at two points where the tension had been too great. These granulated up quickly. Ten days later it was dressed, and fluctuation was noticed in the anterior flap. The cavity was punctured, and two drams of a puriform material escaped. This was not pus, but broken-down tissue which had lost its vitality through the severe contusion of the part. The wound healed within a week.

On June 6th the patient sat up out of bed. A week later he stood on his feet and walked with assistance. On July 1st he was discharged. He then walked without cane or crutch, and limped but slightly. He was seen three months later. He had perfect motion in the right knee, and all other movements were normal. He walked with a barely perceptible halt.

MEDICAL PROGRESS.

Rupture of the Uterus from Dystocia Due to Congenital Displacement of a Kidney.—Albers Schönberg (*Centralblatt für Gynäkologie*, 1894, No. 48, p. 1223) has reported the case of a tertipara whose first labor was difficult and terminated in the birth of a still child at term. The second labor was likewise difficult and protracted, but the child survived. In the third, in which the child presented by the vertex and occupied the second position, the pains suddenly ceased after having persisted for some hours, and vomiting, with symptoms of collapse, set in. The child was extracted with artificial aid, and upon efforts to remove the placenta it was found that the uterus had been ruptured. After delivery, however, the viscus contracted well, and there was no hemorrhage through the vagina. The child was a female of normal size, and weighed about seven pounds. For a time the woman appeared to do well, and a symptomatic course of treatment was adopted. In the course of twenty-four hours, however, vomiting recurred, grew progressively worse, and finally stercoraceous. There was complaint of abdominal pain, with increased tension, and the pulse became bad and rapid. On the fifth day, with a view to the relief of a possible ileus, celiotomy was undertaken, and the abdominal cavity was found to contain a few ounces of free blood. The intestinal serosa was reddened and inflamed; the intestines were distended and adherent. No source of obstruction was found, and the symptoms were ascribed to a condition of paralytic ileus. The abdomen was closed, a loop of intestine being attached to the upper angle of the wound for the purpose of a preternatural anus. The condition of the patient failed to improve, and death speedily followed the operation.

Upon post-mortem examination a cavity was found at the point where the peritoneum is reflected upon the anterior wall of the uterus, containing clotted blood and fragments of disintregrated tissue, and communicating above with the body of the uterus and below with the anterior vaginal vault. Further examination showed that this cavity resulted from a laceration three inches long in the anterior wall of the cervix uteri. The left kidney was found in the concavity of the sacrum, its upper pole lying immediately in front of the promontory and the hilus directed toward the right. The renal artery arose just above the bifurcation of the aorta, and the renal vein emptied into the vena cava in a corresponding situation.

Obstruction of the Duodenum by a Gallstone.—Schüle (*Berliner klinische Wochenschrift*, 1894, No. 45, p. 1015) has reported the case of a woman, thirty-five years old, who for three years had suffered with moderate pain in the right hypochondrium, recurring irregularly, and not associated with jaundice. Four years before coming under observation the patient had vomited a half-pint of blood without preceding or subsequent gastric disturbances. The stomach was distended and somewhat displaced downward. With regulation of the diet and daily irrigation of the stomach the general condition somewhat improved, but vomiting recurred, and the patient was suddenly seized with collapse. On examination, only distention of the stomach was found, but the vomiting persisted despite repeated lavage. The ejected matters contained bile but were not fecal. Symptoms of coma appeared, although the urine contained neither albumin, nor sugar, nor acetone. The quantity of urine was, however, diminished. Intestinal peristalsis was not appreciable, and the conjunctivæ had become slightly icterode. The administration of nutritive enemata and the practice of enteroclysis were followed by the excretion of an increased quantity of urine. The treatment was thus continued until finally a spherical gallstone, 2.7 cm. long, and 9 cm. in circumference and weighing 4.5 grams was extruded from the bowel. Thereafter consciousness returned, and all of the threatening symptoms disappeared.

Two Cases of Cerebral Syphiloma.—At a recent meeting of the New York Neurological Society, Dr. Nammack presented two cases of syphiloma of the brain. The first occurred in a cloth-examiner, aged thirty-four, who six weeks after contracting a chancre suddenly became unconscious, and had no recollection of what transpired during the succeeding forty days. Following this there was right-sided hemiplegia, which confined the man to bed for three months. As soon as the initial lesion was discovered the patient was put on specific treatment, and this was vigorously continued for a long time. About six weeks after the treatment was discontinued the patient developed severe occipital headache and bi-temporal hemianopsia, with ataxia and exaggeration of the knee-jerks. Under specific treatment these symptoms almost entirely disappeared. It is believed that the lesion was probably a gumma situated in the substance of the optic chiasm.

The second patient was a man, forty-four years old, who complained of dizziness, bilateral occipital headache, tinnitus, absolute deafness of the left ear, and diplopia. He also had the characteristic cerebellar gait. The history of syphilis in this case was rather obscure, but under specific treatment the man's symptoms almost entirely disappeared. The diagnosis was gumma in the cerebellar region.

New Operation for the Removal of Myofibromata of the Uterus.—At a recent meeting of the Chicago Gynecological Society Senn described a new method of removing myofibromata of the uterus by celio-hysterectomy. After ligating the broad ligaments in the usual way a circular incision is made around the uterus, dividing the peritoneum and subperitoneal fascia; then the lower segment of the uterus is deperitonized to a sufficient extent to make a cuff, which is sutured to the lower angle of the wound, uniting peritoneum to peritoneum, after which the uterine arteries are tied separately; no use is made of elastic constriction. After the uterus has been brought forward into the lower angle of the incision the upper part of the wound is closed by suturing, which renders the part of the uterus to be removed extraperitoneal before the amputation is effected. If the cervix is left after the amputation of the uterus, the cervical canal is closed by one row of buried catgut sutures. Hemorrhage after ligation of the uterine arteries is very moderate, and is consequently very readily controlled by a number of rows of buried sutures, for which chromicised catgut is invariably used. This leaves a funnel-shaped depression in which rests the cervical stump of the uterus. About twenty-four hours after the operation the gauze is removed and the secondary sutures tied, after which, as a rule, primary union of the wound takes place.

The Influence of Sunlight on Cultures of the Tetanus-bacillus.—As the result of an experimental investigation, WESBROOK (*Journal of Pathology and Bacteriology*, vol. iii, p. 70) was able to confirm previous observations that oxygen is a necessary factor in the destruction of bacteria by light; besides, an actual diminution of the contained air was shown to take place during the time of exposure of cultures in air. The larger the surface exposed the more rapid the destruction when equal volumes are exposed. Existing data do not suffice to explain in what this process consists. Cultures of tetanus-bacilli are completely destroyed on prolonged exposure to the sun in air, though it is possible to stop at a point at which the pathogenesis vanishes while life still remains in the spores. It appeared as if those spores that survived the sun's action are capable of producing, on reinoculation into fresh tubes, quite as virulent cultures as before, but the pathogenesis seems to be increased. It was possible to inject into mice living tetanus-spores without inducing any symptoms. Further research must show whether this result is due to the smallness of the dose, to a temporary attenuation, or to the harmlessness of the spores in the absence of the poison.

THERAPEUTIC NOTES.

A Case of Splenic Leukemia Treated with Bone-marrow.—LAWRIE (*British Medical Journal*, No. 1770, p. 1238) has reported the case of a peevish, miserable child, seventeen months old, that came under observation in an advanced state of emaciation, and with a greatly-distended abdomen. The appetite was entirely lost, and sickness and diarrhea were constant and severe. The skin was harsh and dry, and, with the mucous membranes, extremely pallid. Respiration was rapid and shallow, and the pulse about 120. There was a daily rise of temperature, followed by exhausting perspiration. The urine was free from albumin and sugar. The spleen was immensely enlarged, occupying two-thirds of the abdominal cavity. The anterior edge was easily defined, and extended from the ensiform cartilage to the middle of Poupart's ligament on the left side, and passing well to the right of the umbilicus. The surface was smooth and free from tenderness. The peritoneal cavity contained a slight amount of fluid. Inquiry failed to elicit a history of syphilis or of malaria. A teaspoonful of bone-marrow twice daily was prescribed, in conjunction with appropriate nourishment. Although the case seemed somewhat hopeless, improvement rapidly set in, appetite soon returned, diarrhea ceased, and fever disappeared. The skin and mucous membranes assumed a healthy color, and the child gained in weight. The most striking alteration was the steady diminution in the size of the spleen, which could only be felt in its normal position, under the ribs. After four months of treatment the patient was restored to health and strength.

For Bronchitis.—

℞.—Phenol salicylate	ʒj.
Terpin hydrate	ʒj.
Codein sulphate	gr. ij.—M.

Make twenty capsules or pills.
Dose.—One every four hours.

℞.—Ammonium salicylate . . .	℈ij.
Ammonium carbonate . . .	gr. xxiv.
Ammonium chlorid . . .	℈iv.
Fluid extract of erythroxylon .	fʒiv.
Glycerin (or syrup of bitter orange, or syrup of wild cherry) . .	f℥iss.
Water sufficient to make . .	f℥iv.—M.

Dose.—A tablespoonful every three or four hours.
S. SOLIS-COHEN, *Phila. Polyclinic*, vol. iii, No. 43.

The Employment of Pilocarpin in the Treatment of Pharyngeal Diphtheria and Croup.—As a result of clinical observations in a series of cases, DEGLE (*Wiener medizinische Presse*, 1894, Nos. 50, 51) arrives at the conclusion that, in the treatment of pharyngeal diphtheria and croup, pilocarpin is a more useful remedy than any hitherto reported. Its action, however, is not believed to be specific, but is attributed to the increased secretory activity of the mucous membranes induced. The remedy is not so dangerous in children as experience has shown it to be in the case of adults. The extremely grave cases will not yield to pilocarpin, as they will also not yield to other remedies. In urgent cases, subcutaneous injections may be employed. Under any conditions, early and energetic application of the drug is to be commended.

The Treatment of Whooping-cough.—CHATEAUBOURG (*La Médecine Moderne*, 1894, No. 103, p. 1614) reports a group of five cases of whooping-cough in which injections of guaiacol and eucalyptol were employed with excellent results. The injections consisted of two-and-one-half c.c. of a 10 per cent. solution of guaiacol and eucalyptol in sterilized oil, and were repeated daily. In all instances the symptoms rapidly subsided after the third injection, diminution in the cough being particularly noted; vomiting soon ceased, the appetite was restored, the general condition improved, and the strength conserved.

Treatment of Peripheral Neuritis with Hypodermic Injections of Strychnin.—STODART-WALKER (*British Medical Journal*, No. 1773, p. 1425) has reported three cases of peripheral neuritis in which the subcutaneous injection of strychnin in doses of from gr. $\frac{1}{30}$ to gr. $\frac{1}{30}$, three times a day, was speedily followed by permanent improvement.

The Treatment of Delirium Tremens.—HASKOVEC (*Comp. Rend. Hebd. des Séances de la Soc. de Biol.*, ser. x, t. i, No 33, p. 810) recommends the administration of chloralose in doses of from 4½ to 9 grains, once or oftener, in the treatment of delirium tremens, and reports five illustrative cases.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

PHILADELPHIA.

SATURDAY, JANUARY 26, 1895.

THE FIRST SYMPHYSIOTIMIES IN AMERICA.

IN the month of February, 1894, we received from DR. J. O. WILLIAMS, of William Penn, Texas, an account of three symphysiotomies performed by him: the first on April 29, 1880, at Denison, Texas, the second on July 15, 1884, in Washington County, Texas, the third in May, 1889, in Washington County, Texas. We concluded, of course, that so astonishing a report needed further investigation and proof, and at once set about its verification. Almost a year has been consumed in a voluminous correspondence between the Editor of THE NEWS, in conjunction with the great statistician, DR. R. P. HARRIS, whom we naturally consulted in reference to the matter, and DR. WILLIAMS, as also with many physicians and residents of Texas.

The result of the whole investigation is a mass of cumulative evidence, the details of which we think it unnecessary to publish, that has entirely convinced both DR. HARRIS and ourselves of the truth of the claim made by DR. WILLIAMS.

Instead of publishing the report of the cases just as DR. WILLIAMS had sent it to us, we prefer,[1] for a number of reasons, to epitomize the details and add our own word of editorial comment.

CASE I.—During 1879 DR. WILLIAMS, then of Denison, Texas, was consulted by a girl thirteen years of age, and also by her mother, in reference to the child's pregnancy. They demanded that an abortion should be produced. This was refused, and by a solemn promise of absolute secrecy DR. WILLIAMS succeeded in getting *their* promise to allow the pregnancy to come to term, upon the condition that he would then secretly deliver the child, etc. This was done on April 29, 1880. The girl had been in "violent labor" for eighteen hours, and delivery was only possible by means of the idea, spontaneously occurring to DR. WILLIAMS at the time, of separating the pubic bones by means of a tenotomy-knife. "With one hand the clitoris was depressed to the right side and the blade made to enter as centrally as I could direct, until the point came in contact with the bone. It was then forced upward along the front until the superior margin was reached. I grasped the knife between my fingers and thumb, and, as forcibly as I would risk, drew the blade along the symphysis. The bones yielded and very gently separated before the blade had traversed the entire extent. The bones parted, so that I could depress the overlying tissues and the ends of my fingers between them. I now had no trouble in applying the forceps and delivering the child, which weighed twelve pounds. The mother and child did well." DR. WILLIAMS then went to a dressmaking establishment and gave directions for a laced abdominal and pelvic band, or bandage, which was "applied and was worn for the remainder of the time that I had the patient under charge, probably a month or six weeks."

In connection with this case it will readily be seen that the details of names, the exact place of the operation, the street-number, etc., cannot be published if the promise of Dr. WILLIAMS is to be kept. The interested persons still live, and any such disclosure would at once result in tragedy. But we have in our possession every particular necessary to establish the absolute accuracy of the foregoing report of facts, and can unqualifiedly vouch for their truth as given.

---

[1] One reason for this decision may be gleaned from these words of Dr. Williams in a letter: "Writing or reporting anything of my own work is just as contrary to my inclination and desire as anything I can possibly undertake. If you see proper to allow space in your valuable journal for what I have written, you will have to take the trouble upon yourself of *dressing it up* in fashionable language in keeping with the high tone of your periodical, etc."

The particular reasons for secrecy do not exist in the second and third cases, and these help to furnish indirect proof of the truth of the report of the first case.

CASE II.—DR. WILLIAMS' second operation was performed on July 15, 1884, upon Mrs. S. W. Wicks, of Washington County, Texas. The woman was twenty-three years of age, and this was her first pregnancy. She had been in labor "many hours." "I found a badly contracted and disturbed pelvis. I tried to separate the bones, as in Case I, with the tenotomy-knife, but failed. I then used a probe-pointed curved knife, placing the extremity of the cutting surface of the blade on the superior margin of the symphysis, forcing the blade through the overlying tissues, and as the blade came down upon the bone the handle of the knife was elevated so that the point or extremity was maintained in close proximity to the posterior surface of the symphysis, and, guiding it by the finger of the other hand in the vagina, the blade was carried down until the large part of the blade was in contact with the bone. I now exerted all the pressure permissible, and after much worry and some discouragement I discovered the bones yielding. I withdrew the knife, and, as the contraction renewed, I made pressure over the fundus. The bones now parted, and I applied the forceps, but failed to deliver. I now perforated the head, again applied the forceps, and effected delivery. I drew the one-and-one-half inch flesh wound together with adhesive strips, and placed on a nice-fitting bandage. The woman was up and said she felt well on the twelfth day."

As a bit of confirmatory testimony the following affidavit, copied from the original in our hands, may be appended:

Newton County, Ga.:

I, S. W. Wicks, do hereby certify that I lived in Washington County, State of Texas, in the year 1884; that on the 15th day of July, in said year 1884, I was confined, and that Dr. J. O. Williams, of Penn, Texas, attended me during said confinement. There was some trouble in getting the child from me that I cannot exactly explain; but afterward the Doctor (Williams) told me he had tried to save the child, but could not do so. He said that he had *separated* the bones in my hips in order to get the child from me, and that I would be compelled to remain sometime in bed, keep quiet, and be carefully looked after, or I would suffer afterward, and may be never get well. I was kept *bandaged* and my limbs together. I felt so well that on the twelfth day I was up all day. I had been up several times for a short while before this, but was up all day on the twelfth day—went visiting in three weeks. I have felt no bad effects since then from my difficulty. On October 1, 1886, I gave birth to a son, who is now alive.

S. W. WICKS.

Sworn to and subscribed before me, this June 18, 1894.
[SEAL.] JOHN B. DAVIS,
Clerk Supreme Court, Newton Co, Ga.

CASE III.—This operation was performed in May, 1889. The patient was a negress, about eighteen years of age. She had been in convulsions for thirty hours, with pains similar to those of labor for two or three days before. "I found the pelvis so contracted transversely that it was with some difficulty that two fingers could be passed. I at once decided upon pubo-symphysiotomy, which was readily accomplished as in Case II. The forceps was applied, the child delivered, and with much difficulty resuscitated. The report was that the woman 'had not passed urine since the fits had set in,' and probably not for a day or two before that time. The woman died, but the child lived."

The following affidavit, with other testimony, is confirmatory of the foregoing report:

THE STATE OF TEXAS,
County of Washington:

Before me, the undersigned authority, on this day, personally appeared B. F. Dotson, who, being by me duly sworn, deposes and says, that he was present and assisted Dr. J. O. Williams in attending a negro girl who had been having labor-pains about four days under the attention of a woman, but could not give birth to the child. She had been having convulsions for several hours before I knew of her being seriously ill; they were renters on my place. I told the husband of this woman to go for a doctor or he would have a dead wife. The woman was unconscious and having frequent convulsions.

I sent for Dr. J. O. Williams myself. He came, and tried to take the child, but failed in doing so.

He spoke to the relatives about opening the belly and removing the child that way, but they were not willing to that. I told the Doctor to go on and do as he thought best, and that I would assist in any way I could. I held the legs in suitable position and the Doctor passed a knife-blade in center of the hip-bones, and they separated so that in a few moments he could take the child, which after some time begăn to breathe, and got along all right and lived about one year.

The woman had been in convulsions all this time, and remained so to her death, about three days afterward.

Her hips were bandaged tightly, but she would sometimes jump out of bed, and I think one time ran out of the house.

I heard the Doctor say that he performed the same operation in relieving a lady, Mrs. W., who some years ago lived on my place and was in the same house as this girl now was.

The operation upon the girl in which I assisted was in May, 1889. The one upon Mrs. W. was, I think, about four years before this. B. F. DOTSON.

Sworn to and subscribed before me, this March 14, 1894. [SEAL.] E. P. CURRY,
County Judge of Washington County.

This is to certify that I know Mr. B. F. Dotson personally, and that he is an extensive farmer and prominent man of this county, and perfectly reliable in every respect. E. P. CURRY,
County Judge of Washington County.

We could easily fill a whole issue of THE MEDICAL NEWS with details and incidents in connection with these cases, especially of the first, and with excerpts from the letters of DR. WILLIAMS, and every line we are certain would be voted of absorbing interest by our readers. We almost regret the lack of space to do so, and at least wish that a historic essay might be written concerning the matter. We can imagine no novel of more intense interest, no sociologic study more bountiful in instruction. Here was a man who spontaneously conceived and thrice carried out the operation of symphysiotomy before any American surgeon. He was frankly deficient in preliminary education and placed in a frightful tangle of most distressing and possibly tragic circumstances, no hint of which we have been able to give. He was surrounded by a set of conditions the dramatic interest of which we have scarcely seen equalled upon the stage. Through it all he has carried himself, and out of it all he has brought himself, with a combination of shrewdness, and modesty, and probity beyond all praise. We cannot forbear a short characteristic quotation from one of his private letters:

> I care not how successful a doctor is, or how many affixes he can lawfully link with his name. Or of what religious denomination he is a *faithful* follower of—aggressive or conservative in his professional life it makes no difference, he will have a neighbor that would not permit him to *doctor* his *unfaith*ful hound. My idea is that every individual has individual rights and privileges, that will not interfere with those of others, and then a *general* governing principle that surmounts, pervades and limits this physical life of ours, so that the life of one that tends to perfect *the Ego*, and at same time lends honor to the general body or unity; that has an *honest*, firm purpose, and the determination to "hew as near the conceived line of truth as possible, the chips falling where they may," constitutes the life of a true man. Educated or illiterate the measure holds good and the article is so many Carats fine in proportion as *opportunities* have been *rightfully* utilized—just *how we've improved ourselves* and *governed* is the *weights* upon the beam of life's scale.

The chief lesson that springs to view is one that has been summed up in the expression of DR. HARRIS: *In your reports and statistics, wait until you hear from the backwoods.* "The backwoods" are often deficient in literary qualities, and in many of the arts of modern medicine, "push" and self-assertion included, but they are often profoundly ingenious, and not seldom exhibit an unchronicled heroism quite equal to any that vaunts itself in populous places.[1]

THE NEED OF A DEPARTMENT OF HYGIENE AT WEST POINT.

THE report of the Committee on Hygiene and Athletics, composed of Messrs. W. W. KEEN, JOHN C. BLACK, and JOHN J. DAVIS, of the Board of Visitors of the United States Military Academy at West Point, contained in the report to the Speaker of the House of Representatives (for the year 1894), contains some points of exceptional interest. That the sanitary conditions prevailing at West Point are good is seen by the fact that during the year no case of infectious disease occurred among some 1300 students. For the large amount of eye-strain that is evident, one-fifth of the cadets requiring glasses, the committee makes some excellent suggestions as to ocular hygiene. But we fear the committee leans too much toward the old-time view that eye-strain arises from poor light, from level instead of sloping desks, etc., whereas the truth must be acknowledged that if ametropia exists (and exist it does in much greater degree and more frequently than is supposed), all the hygiene, so-called, in the world will not replace the need of correcting glasses.

The committee has made the astonishing discovery that the entire instruction in hygiene at West Point is "limited to six advance lessons (and five review)," and one lecture on first aid to the injured. That this is ludicrously insufficient will be evident to anyone giving the subject a moment's consideration. We cannot, however, forbear quoting the wise words of the committee:

> The sanitation of armies during war is not merely a medical question. However desirable the medical requirements may be, military necessities may make it

---

[1] Dr. Joel O. Williams is well known to me through a long and voluminous correspondence not yet ended. I regard him as a man of strong individuality, a lover of truth, and reliable in his statements, from principle and moral training. B. F. Dotson, who aided him in his third operation, was at one time a student of medicine. Mrs. Wicks is a widow, and reported to me as a good, reliable woman by those who knew her in Newton, Georgia. The child of Case 1 is thought to be living.—ROBERT P. HARRIS.

needful to disregard them, even at serious risk to the health of the army. But in probably the majority of cases this is not true, and when not so the importance of the proper location and sanitation of camps and barracks and of those medical precautions which may be highly conducive to the health and therefore to the success of an army should be fully understood by the officers of the staff and line, so that they may appreciate their stringent necessity and act in accordance with them, instead of inviting disaster by their violation. This violation will be none the less injurious or even fatal to the military success of an army because it is committed unintentionally and purely from ignorance of the laws of health, for these laws require obedience and enforce their own penalties as rigidly as the laws governing military operations themselves.

In addition to this it needs no argument to convince any intelligent man of the importance of every soldier and officer knowing how to render effective first aid to the injured and wounded, especially in an occupation one of whose chief objects and dangers is the infliction and reception of such wounds and injuries. In fact, in the past, especially in small commands on duty without a medical officer, most valuable lives actually have been lost to the army and the country for the want of exactly such knowledge. Instruction in first aid is given with reasonable fulness to the soldiers at this command, as each of them serves in turn as a company bearer. Prospective officers should certainly be as well instructed as their men, and if possible better.

The suggestion that there should be a chair of anatomy, physiology, hygiene, and first aid to the injured, commends itself as a most belated and much-needed step in progress. Surely some of the 565 hours devoted to chemistry, mineralogy, and geology might profitably be given to health.

As to athletics, the committee rightfully praises and commends its cultivation. But as to foot-ball there is a noteworthy qualification. The comparative statistics offered are the only ones in existence that can lay claim to scientific accuracy.

From them we quote as follows:

TOTAL INJURED.	
Foot-ball	54
Riding	17
Gymnasium	9
Total	80

Injuries in riding and gymnasium usually very slight.

Days lost from—

Foot-ball accidents	277
Injuries in riding	57
Injuries in gymnasium	11

Per cent. of accidents per man in—

	1892.	1893
Foot-ball	01.05	01.6
Riding	0.11	0.09
Gymnasium	0.10	0.08

Per cent. of days lost per man in—

	1892.	1893.
Foot-ball	3.93	8.01
Riding	0.35	0.31
Gymnasium	0.10	0.15

Per cent. of men off duty per diem in—

	1892.	1893.
Foot-ball	1.18	3.01
Riding	0.79	0.63
Gymnasium	0.64	0.12

Per cent. of days lost per accident in—

	1892.	1893.
Foot-ball	2.98	5.01
Riding	2.74	3.04
Gymnasium	5.80	1.02

To obtain the comparative percentage of foot-ball and riding accidents multiply the percentages of foot-ball accidents by 3, as foot-ball is only played once a week, and riding is done three times a week.

To obtain the comparative percentages of foot-ball and gymnasium accidents multiply the foot-ball percentage by 6, as the exercise in the gymnasium is taken six times a week.

The committee concurs in the Superintendent's advice that the interacademic games be abandoned.

EDITORIAL COMMENTS.

Successful Celiotomy for Perforating Typhoid Ulcer with Peritonitis.—The most alarming, as well as the most fatal, complications of typhoid fever are intestinal hemorrhage and intestinal perforation. Recovery may ensue after either, although it cannot be said that much can be done medicinally to favor such a result. In the nature of things the danger is less great from hemorrhage than from perforation, although, as intimated, cases have been reported in which it was believed that recovery followed intestinal perforation. In view of all of the circumstances and particularly of the fatality of the complication if left to itself, the only logical mode of treatment seems to reside in operative interference The number of instances in which the surgeon has intervened is as yet not a large one, and although the results have not been invariably as favorable as they might be, enough has been demonstrated to show that the operation is a life-saving one, and the proportion of successes must increase as the occurrence of the complication is recognized early and the cases come immediately under the notice of the surgeon. To the successful cases already on record is to be added another in the hands of an American surgeon.

Abbe (*Medical Record*, No. 1261, p. 1) has reported the case of a young married woman, twenty-one years old, who, in the third week of an attack of typhoid fever, when convalescence appeared to be setting in, was seized with great pain associated with a feeling as if something had suddenly given away in her abdomen below the umbilicus. The woman vomited, became much collapsed, and the temperature rose rapidly to 102°; great pain and tympanites were present. Perforation was suspected and the patient was kept absolutely quiet, poultices being applied to the stomach, and sufficient morphin being given to allay the great pain. The temperature fell somewhat, but for two days ranged between 102° and 102.5°. The vomiting subsided, but the tympanites continued. At the end of the second day the woman's condition became suddenly worse, the pulse grew weaker and the abdomen greatly distended.

It was now determined to operate, and a median incision below the umbilicus exposed distended coils of deeply-congested and greatly-inflamed intestine smeared with sticky lymph. The pelvis and lower abdomen were filled with a collection of foul, purulent, and fetid intestinal extravasation. This was feebly confined by matted coils of intestine loosely glued together and which broke apart on being touched, but, being recognized, permitted the introduction of clean celiotomy-sponges. Under the upper abdominal wall a few coils were seen that showed more recent inflammation. Two pints of foul, purulent fluid and thick lymph were cleaned out and the abdomen irrigated with warm and weak sublimate solution, 1 : 20,000, followed by plain warm water. In the lower part of the ileum were found many thick, oval patches, having their long axes parallel to that of the bowel, easily identified by touch as the intestine passed through the fingers, and shown also by increased subperitoneal hyperemia. One such inflamed Peyer's patch presented a gangrenous perforation a quarter of an inch in diameter, from which intestinal contents were seen to make their exit. The opening was closed by interrupted silk sutures, over which two layers of mattress stitches were placed, as these were the only sutures that would hold in the tender and inflamed intestinal coat. A large abdominal tamponade of iodoform-gauze was placed within the abdomen and pelvis, and no attempt was made to close the wound. An enema of hot black coffee and whiskey assisted greatly in preventing shock. The patient was put back to bed in three-quarters of an hour from the beginning of anesthesia. She passed a good night and had a strong pulse on the following morning. The tympanites was also less.

At the end of forty-eight hours the patient was in good condition, when the tamponade was replaced by a new and loose one and five grains of calomel were administered. A little fluid feces leaked from the wound after the action of the calomel, and continued so to do for two weeks. The abdominal wound pursued the usual course, closing in rapidly by granulation and leaving a narrow and firm scar. After the third day the appetite improved and rapid convalescence ensued.

The Murderer and the Ocular Photograph.—The student of psychology, both morbid and sociologic, finds nowhere better material than in medical superstitions. The immortality of these superstitions is wonderful. They are not affected by civilization, and the growth of science and of common sense leaves them untouched. Of late the newspapers of the land have been immensely interested in the astonishing exhibitions in the eye of a murdered woman of the photographic image of her murderer. The "local scientist" examines the dead woman's eye, and by "a magnification of 400 diameters" he finds plainly the image of a "man's form." Coroner, clergyman, and others saw the startling photograph. There is something not a little pathetic in the impulsive desire on the part of poor humanity to find that divine retribution has contrived some secret means whereby crime shall be found out. But when we read the account carefully we find that in the present case the "local scientist" examined the dead woman's eye as it rested naturally in the socket. That, of course, means that he examined the cornea, because without the aid of the ophthalmoscopic principle the retina of the undissected eye is still as invisible as it was before Helmholtz invented the ophthalmoscope. But, unless the woman wore biconvex lenses of some thirty or more diopters, how, in the name of optics, would an image be formed upon the cornea? This leaves out of the count the facts that nobody ever wore such lenses, and that if one did no image could be formed of the murderer a few feet away, and that the cornea is a light-transmitting structure, without any analogy to that of the retina or a photographic sensitive plate. We suppose that this kind of popular science had in mind a vague echo of the experiments with the visual purple of the retina, which seemed to give some warrant for the belief in retinal fixation of the last image seen before death. But the unconscious transferring of the seat of the changes to the cornea was as remarkable for blundering and for jumping to conclusions as such science could well be. It is this condition of mind that makes visible what does not exist and that renders human testimony as regards certain things utterly valueless.

The Lancet Relief Fund.—The Sixth Annual Report of the Almoners of the Lancet Relief Fund shows a continuance of the good work for the prosecution of which the Fund was instituted. Every January the proprietors of the great metropolitan medical weekly whose name the Fund bears provide $1500 for the Fund, which is administered free of cost by a committee of almoners consisting of the President of the Royal College of Physicians of London, the President of the Royal College of Surgeons of England, the President of the General Medical Council, Mr. Thomas Wakley and Mr. Thomas Wakley, Jr. The Fund has for its object the rendering of immediate pecuniary assistance to registered medical practitioners or to the widows or orphans of members of the profession in cases of distress and emergency, by the grant of money by way of loans free of interest, or gifts, as the circumstances of the various cases may require. During the year 1894 the sum of $1720 was granted in relief, while repayments of loans to the amount of $105 were made. There were fifty-six applicants for relief; assistance was afforded in twenty-six of these, the amounts granted ranging from $25 to $150.

Foot-ball Impetigo.—To the opprobrium under which the game of foot-ball already rests is yet to be added the responsibility of causing a peculiar form of cutaneous disorder. For the purpose of obtaining information as to the etiology, nature, and treatment of the affection, which was recently prevalent among English foot-ball players, the Council of the Medical Officers of Schools Association of London has issued an appeal asking for data as to (1) the nature of the site upon which the school stands, whether the pupils are affected or not; (2) whether Association or Rugby foot-ball is played; (3) the nature of the disease, particularly as to its contagiousness; (4) the prophylactic and curative treatment proper to the disease. The disorder is believed to be contagious, and occurs principally on the face, ears, and neck, and sometimes on the hairy scalp. It successively passes through stages of erythema, papule, vesicle, and purulent crust.

Attendance of the Medical Colleges of the United States and Canada.—From statistics gathered by the *Journal of the American Medical Association* it is estimated that the aggregate attendance of the medical colleges of the United States and Canada for the session of 1894–95 will reach 20,800, as compared with 18,500 for 1893–94, and 18,340 for 1892–93. The great gain of the session of 1894–95 is found to be at the expense of higher medical education (which is made to stand for a lengthened term of study); for while in 1893–94 there were 803 four-year students, there were but 781 in 1894–95. The following comparative figures are given as the relative number of students to the population in various countries: In the United Kingdom 1 : 5286, in France 1 : 7776, in Germany 1 : 5757, in the United States and Canada 1 : 3365.

The Annual Report of the New York State Board of Health contains some interesting data. The death-rate for 1893 was 19.50; for 1892, 20.78; for 1891, 21.43; and for 1889 and 1890, 19.65. The highest mortality occurred in the months of March and July, the lowest in June and November. The mortality among children under five years of age was 33.6 per cent. of the deaths at all ages. Zymotic diseases caused 180 deaths in every 1000 deaths from all causes. During the year 1893, 20,310 cattle were examined for tuberculosis, at an average cost of 47 cents per head; 687 were found to be tuberculous, and were therefore killed. The diagnosis was based upon reaction to injections of tuberculin. Eight samples of butter were examined bacteriologically, some having been prepared from the milk of tuberculous cows, but no tubercle-bacilli were found.

NEWS ITEMS.

The Cleveland Medical Society at its annual meeting, held recently, elected the following officers: *President*, William E. Wirt; *First Vice-President*, Augustus F. House; *Second Vice-President*, Henry S. Upson; *Recording Secretary*, W. F. Brokaw; *Corresponding Secretary*, Frank S. Clark; *Treasurer*, N. Stone Scott; *Librarian*, William E. Bruner; *Censors*, M. Rossenwasser, Howard S. Straight, L. B. Tuckerman, A. J. Cook, W. J. Scott; *Pathologist*, A. P. Ohlmacher; *Trustees*, H. G. Sherman, Charles Gentsch, C. F. Dutton. The society has 291 members. The average attendance for the year was 135. The society meets every two weeks.

Correction.—By an inadvertence it was announced in THE NEWS of January 19th that the next meeting of the Pennsylvania State Board of Medical Examiners will be held on February 14th, whereas the date should have been February 12th. We would also correct the statement in the same number as to the examination of bacteriologists for the positions of bacteriologist and assistant bacteriologist of the Philadelphia Bacteriologic Laboratory. The examinations are open to all, whether residents of Philadelphia or not, and the appointees being under civil service regulations are not subject to removal by "political" changes or influences.

A National Congress of Tuberculosis is to be held in the buildings of the University of Coimbra, Portugal, on March 24th, which is the date on which Koch announced his discovery of the tubercle-bacillus.

Prof. J. Burdon Sanderson has been appointed Regius Professor of Medicine in the University of Oxford, in succession to Sir Henry Acland.

A Statue of Helmholtz is contemplated in Berlin. The German Emperor has expressed a willingness to contribute $2500 to a fund for the purpose.

Medical College Amalgamation.—It is announced that the Chicago College of Physicians will consolidate with the University of Illinois.

Sir Joseph Fayrer has retired from the office of President of the Medical Board at the India Office in London.

Lady Paget, wife of Sir James Paget, died January 7th, at the age of eighty years.

THE TREATMENT OF COMPOUND FRACTURES.

BY EDWARD HAMILTON PERSHING, M.D.,
OF LAWRENCE, LONG ISLAND.

IN no class of surgical cases have the results of antiseptic treatment offered a greater contrast to those obtained in the pre-antiseptic days than in compound fractures. One of the leading surgeons of New York, who was once an interne of Bellevue Hospital, has repeatedly stated that during the eighteen months of his service there every case of compound fracture of the femur brought to the hospital, and there were a great many, died of septic infection. In contrast to this appalling record, the same institution, or any other modern city hospital, could to-day show case after case of severe compound fracture in which not only has life been saved, but a useful limb as well, and in which pus has not at any time been found in the wound. There is apparently very little recent literature on the subject of the treatment of compound fractures, most treatises on fractures dismissing it with the general statement that the wound should be treated on the usual antiseptic principles, and the fracture put up in a suitable retentive apparatus. It would seem that some account of the practical details of treatment of these cases as they occur in the service of a general hospital would have a certain value.

That the sound principles of antiseptic surgery, as applied to compound fractures, are not even now universally accepted is shown by the presence of an article in a current medical journal advocating the use of poultices. The writer assumes that suppuration is inevitable, and thinks poultices would hasten the appearance of pus and tend to prevent septic absorption. He is sufficiently impressed, however, with the value of asepsis to suggest that the poultice might be rendered aseptic by the addition of carbolic acid, and that by changing it every hour the possibility of its becoming a culture-field for germs might be prevented. It would seem scarcely necessary to point out that any dressing requiring such frequent changing would be a most unfortunate one for a fracture, and it is hardly possible that poultices will ever again become a favorite dressing for an open wound, even with the concession to cleanliness implied in the addition of carbolic acid. However, it is not at all necessary to assume that even the most unpromising compound fracture is certain to suppurate, as the following report of twenty cases clearly shows. These cases occurred in the services of Dr. C. K. Briddon and Dr. A. J. McCosh, in the surgical division of the Presbyterian Hospital, New York City, during a period of about six months.

Pus appeared in the wound of but one case treated in the hospital. In another, although the wound did not suppurate, and the patient appeared to be doing well, symptoms of tetanus appeared on the twelfth day, and the man died a week later. In a third case the patient left the hospital against advice, on the second day after the injury, and reappeared one week later with the wound infected. In all the other cases the wound remained clean throughout, healed readily, and a practically perfect result was obtained in each.

All of these patients were subjected to the ordinary dangers of infection from dirty clothing and dirty surroundings at the time of injury. Many of them received their injuries in the street, and the street-filth was liberally rubbed into their wounds. Some had, in addition to the broken bone and the wound leading to the point of fracture, extensive laceration and contusions of the surrounding tissues. The fact that such cases as these last escaped suppuration would certainly show that every case ought to be treated with the distinct purpose of rendering the wound aseptic, and keeping it so, and in no case should this be regarded as hopeless.

The general line of treatment was in all cases the same. Most of them were brought in by the ambulance. When the bone was found protruding from the wound no attempt was made by the ambulance-surgeon to reduce the deformity, on account of the liability of introducing dirt or other infective material into the depths of the wound. A liberal dressing of iodoform-gauze and sterilized gauze was applied to the wound, the limb immobilized by a suitable splint, and the patient taken at once to the hospital. Here an anesthetic, usually ether, is given. The limb is shaved, scrubbed with green soap, followed by ether, and finally irrigated with a solution of mercuric chlorid of 1 : 1000. The wound, protected during the cleansing of the skin by packing of iodoform-gauze, is now irrigated with bichlorid solution 1 : 1000. This should be done very thoroughly, in many cases as much as two or three quarts of the solution being used. From this point the same details are scrupulously observed as in any surgical operation.

The site of the injury is surrounded by sterilized towels. All instruments are boiled, and the hands of the surgeon and assistants are of course carefully disinfected. An examination of the wound is made; the position of the fragments, the amount of comminution, and the extent of laceration of the soft parts are accurately ascertained, remembering also the possibility of injury to the large vessels and nerves in the neighborhood. When there is much subcutaneous laceration, caused by the violent movements of ragged fragments of bone, the skin over the lacerated muscles should be opened up by liberal incisions and the wound again thoroughly irrigated with bichlorid solution. The incisions give to the irrigating fluid certain access to all parts of the wound, and also insure perfect drainage later, when the wound is packed with gauze. When it is remembered that infective material has been carried into the depths of nearly all these wounds before they come under treatment, the thorough opening up of all recesses and pockets seems most important. If the bone is comminuted, small loose fragments are removed. The deformity is then reduced, the fragments being brought into apposition, and the limb is held in the most perfect position possible, while the wound is packed with iodoform-gauze, and a large dressing of sterilized gauze applied. A few narrow strips of bass-wood splint, soaked in bichlorid solution and bandaged to the limb with a sterilized bandage, afford an additional precaution against the fragments slipping out of position during the application of the splint. A layer of sterilized cotton is bandaged over these coaptative splints, and the limb is put up in a suitable immobilizing apparatus. In nearly all the following cases a splint of plaster-of-Paris was used.

In those cases in which the fragments readily slip out of position, and when it is difficult or impossible, by simply holding the limb in position, to retain them in accurate apposition, it may be necessary to fasten them together with sutures of silver wire or silkworm-gut. In the great majority of cases this will not be called for, but two in the following list have been so treated.

When the wounds in the soft parts are extensive it is an open question as to whether, after disinfection, they should be partially closed by sutures. Some cases treated in this way have given results that were all that could be desired. There are certain considerations, however, that strongly argue in favor of leaving the wound entirely open and packing it throughout with gauze. No time can be saved by sewing it up, since, even when left open, the wound in the soft parts will be healed before the bone has united with sufficient firmness to permit active use of the limb. But the consideration of greatest weight in determining treatment is the additional security against suppuration which is obtained by leaving the wound open, and packing it throughout. As suppuration is the usual cause of failure to obtain a good result, every possible safeguard against it is of importance, and it is always to be remembered that we are dealing with a wound infected from the beginning.

The splint is removed and the dressing changed for the first time in ten days, or two weeks after the injury, unless pain or a rise of temperature should render an earlier examination of the wound advisable. At this time any malposition of the fragments can still be corrected, as there will not be any appreciable union. The following cases were all treated as described, with such modifications as the peculiarities of each demanded:

Case I was a boy, sixteen years of age. While running he fell down an embankment a distance of fifteen feet, striking on a large stone. Examination revealed a compound fracture about the middle of the right femur. The upper end of the lower fragment was protruding from the wound, which was on the outer side of the thigh. There was considerable subcutaneous laceration of the muscles. After cleansing of the limb, the patient being under ether, the wound was irrigated with a bichlorid solution 1 : 1000. It was then enlarged by incisions through the skin exposing the lacerated tissues beneath, and again irrigated. It was somewhat difficult to bring the fragments into exact apposition, but this was accomplished by firm traction on the limb. The wound was then packed with iodoform-gauze and a large dressing of sterilized gauze and sterilized absorbent cotton applied. The straps for a Buck's extension-apparatus were placed in position, running well above the knee on either side, and the entire limb was then put up in a plaster-of-Paris splint, running from the toes to the groin. A weight of fifteen pounds was attached. The highest temperature was 101°, on the second day after the accident. The splint was cut down and the dressing changed on the tenth day. The wound was clean, and there was no appearance of any inflammatory action. The wound was washed out with hydrogen dioxid and bichlorid solution 1 : 5000, repacked and dressed, and a new plaster-splint applied as before. The dressing was changed, and a new splint applied every two weeks. The wound was entirely healed in eight weeks, no pus having appeared in it at any time. Union of the fracture was delayed, but finally became firm. When seen, six months after the injury, there was no deformity, and the limb was as useful as the other.

Case II was a boy, eight years of age. He was run over in the street by a coal-cart, the wheel passing over his right thigh. Examination under ether showed a fracture of the femur, near its mid-point, with a large, ragged wound leading directly to the point of fracture. The tissues were much torn and contused. After cleansing the limb the wound was irrigated with bichlorid solution 1 : 1000. There was ready access to all parts of the wound, rendering any enlargement unnecessary. The bony fragments were so shaped that they could be interlocked in apparently perfect position. On this account the leg was put in a plaster-of-Paris splint, without the addition of a Buck's extension-apparatus, after the wound had been packed with iodoform gauze and a copious dressing of sterilized gauze and cotton applied. The splint was carried above the thigh by means of a spica of the hip, thus immobilizing this joint. There was no rise of temperature, and but little pain. The splint was removed and the dressing changed on the tenth day. There was no pus or evidence of inflammation about the wound, but it showed some tendency to sloughing where the contusion had been greatest. It was irrigated with hydrogen dioxid and bichlorid solution 1 : 5000, loosely packed with iodoform-gauze, and dressed with sterilized gauze and cotton as before. Although the position of the fragments was apparently perfect, the possible danger of shortening of the limb made it seem safer to apply a Buck's extension-apparatus. This was done, the straps being carried almost to the point of fracture. Immobilization of the fragments was secured by means of coaptation-splints of tin, cut to fit the contour of the thigh, and fastened to it by means of straps and buckles. This line of treatment was continued, the wound being dressed once a week. There was no pus at any time. At the second dressing all sloughing had ceased, and the wound was beginning to granulate freely. In nine weeks the wound was healed, and union was firm, with no shortening. When seen four months after the injury the boy walked with no evidence of having been hurt, the result being practically perfect.

CASE III was a boy, thirteen years of age. While riding a bicycle he collided with an ice-wagon. The wheel of the wagon is said to have passed over his left leg. The handle of the bicycle was driven into the tissues of the left thigh on its outer aspect. Examination under ether showed an extensive lacerated wound on the inner side of the knee, extending into the popliteal space and exposing the inner hamstring tendons. The internal saphenous vein was torn across. A punctured wound on the outer side of the lower third of the thigh also extended into the popliteal space communicating with the wound on the inner side. The posterior ligament of the knee-joint was torn away, and the finger passed readily into the interior of the joint. The popliteal artery and vein were intact, though it was difficult to understand how they escaped injury. There was a fracture of the lower end of the femur, the line of fracture running from the upper boundary of the external condyle, obliquely downward and inward into the knee-joint. Hemorrhage at the time of the accident was so severe as to require the application of a tourniquet to the femoral artery. The wound was thoroughly irrigated with a solution of mercuric chlorid 1 : 1000, after the limb had been cleansed as described. The punctured wound on the outer side of the lower part of the thigh was found to run downward through the lacerated subcutaneous tissues to a point opposite the head of the fibula. This was laid open by an incision through the skin, and the whole wound again washed out. The tourniquet was removed and all bleeding vessels caught and tied. The fragment of femur was placed in as perfect a position as possible, and the wound packed with iodoform-gauze, one narrow strip running into the cavity of the knee joint to secure free drainage. The limb was put up in a long, posterior Volkmann splint, reaching to the ischial tuberosity. The patient was suffering acutely from shock and loss of blood, and had to be freely stimulated with whiskey and strychnin hypodermically. The temperature did not rise above 101.5°, and the patient made an almost uninterrupted recovery. The dressing was changed on the eighth day. No pus was found in the wound, and it was washed out with hydrogen dioxid and bichlorid solution 1 : 5000, and loosely packed with gauze. Subsequent dressings were made once a week, and this treatment repeated. In eight weeks the wound had healed except for a healthy granulating ulcer, and there was firm union in the fracture. There was also some motion in the knee-joint, though the boy still wore a posterior splint in going about the ward. Two weeks later the splint was removed, and he was encouraged to use the limb, flexing and extending the leg as much as possible. Four months after the injury he walked without a limp. The wound was entirely healed, and flexion and extension at the knee-joint were perfectly restored.

CASE IV was a man, thirty-eight years old, who fell down a well a distance of ninety feet, receiving numerous contusions and a compound fracture of the right patella, evidently caused by direct violence. The patient was first seen about fifteen hours after the accident, and no attempt had been made to cleanse the wound. It was bound up in dirty rags, and part of it was covered with a large paster-ballot, applied directly to the bleeding tissues. Examination under ether showed the tissues over the patella to be much torn and bruised. The line of fracture was transverse and near the middle of the bone. On the outer side there was some comminution, a number of small fragments being removed. The joint-capsule was extensively lacerated, and especially so on the outer side. There were marks of contusions involving most of the limb, from the lower part of the thigh to the foot. The skin having been cleansed as usual, the wound and joint-cavity were washed out with solution of bichlorid 1 : 10,000, several quarts being used. The joint-cavity was again irrigated with sterilized water. The fragments of the patella were united by means of sutures of silkworm-gut, one passed deeply through the insertion of the quadriceps extensor tendon at the upper border, and one through the ligamentum patellæ at the lower border. The free ends of these two sutures were tied over the anterior surface of the patella, thus securing and maintaining accurate apposition of the fragments. The sutures running over the anterior surface of the bone acted as splints and prevented any tilting of the fragments. The torn periosteum over the anterior surface of the patella was united by a few sutures of fine silk. The tear in the outer side of the capsule of the joint was also partly closed by sutures of catgut, leaving an opening large enough to accommodate a good-sized tampon of iodoform-gauze, which ran directly into the joint, to serve as a drain. Other tampons of gauze were carried into the depths of the wound in the soft parts, and a large dressing of sterilized gauze and cotton applied. The leg was put up in a long posterior Volkmann splint. The temperature rose rapidly, reaching 102.5° on the day after the operation, and 103.5° on the next day. The wound was then dressed and found full of pus. It was thoroughly washed out with hydrogen dioxid and bichlorid solution 1 : 5000, and loosely packed with iodoform-gauze, so as to give the freest possible drainage. The next day there was no improvement, the temperature being still high and the local process unchecked. A continuous irrigation of iced bichlorid solution, 1 : 10,000, was then begun. This caused a fall in the temperature and some lessening of the discharge of pus. All hope of union in the patella was abandoned, and the sutures removed, thus completely opening up the wound. For four weeks the improvement was slow, the temperature in the afternoon being from 100° to 101.5°. In spite of daily dressings it was impossible to stop the suppuration. Occasionally there would be some burrowing of the pus. The undermined tissues were promptly laid open by incisions as soon as discovered, and the sinuses washed out with hydrogen dioxid and bichlorid solution. The original infection appeared to have been a very virulent one, and the extensive areas of contused tissues offered an admirable culture-ground. About six weeks after the injury the patient began slowly to grow worse. The afternoon temperature gradually grew higher, and his general condition was not so satisfactory. The process at the knee was still slowly improving, and showed nothing to account for the change. A new focus of suppuration was discovered, however, in the bruised tissues about the ankle. This was treated in the same way, being promptly opened up, washed out, and dressed daily. In spite of every effort to check the process, however, it slowly advanced, and finally invaded the ankle-joint and the joints between the tarsal bones. The temperature now reached 104° and 105° in the afternoon. There was profuse sweating and occasional chills. The symptoms of septic intoxication finally became so serious that amputation of the thigh was decided upon in order to save the patient's life. This was done nearly three months after the original injury, and improvement began at once. The temperature became normal for the first time since the accident, the amputation-wound healed readily, and the patient rapidly regained health and strength.

I have given the details of this case rather fully, because in its course and final result it offers such a vivid contrast to the other cases described. Nothing could more clearly emphasize the importance of avoiding infection when possible. The causes of the unfortunate course and termination in this case are to be found, I think, first in the length of time between the injury and the first attempt to cleanse the wound, and, second, in the extensive contusions, which must have diminished the natural resistance of the tissues.

CASE V was a man, forty-three years of age, who fell while running, receiving a fracture of both bones of the left leg. Examination showed a ragged wound over the inner side of the lower third of the tibia, evidently produced by the protrusion of a fragment of bone. There was a fracture of the fibula at the same level. Under ether the limb was thoroughly cleansed, the wound irrigated with mercuric chlorid solution, 1 : 1000, and enlarged sufficiently to open up all pockets and sinuses. A number of small detached fragments of bone were removed, and the wound again thoroughly washed out. There was considerable misplacement of the fragments, and the deformity, though easily reduced by means of traction and direct pressure, recurred readily. The desirability of wiring the fragments together in order to secure accurate position was discussed, but it was finally decided to have an assistant carefully hold the foot in position, aided by an orderly holding the leg above, while the wound was packed with iodoform-gauze and a dressing of sterilized gauze applied. Over this dressing a number of strips of bass-wood splint were strapped with adhesive plaster to maintain the position, while a splint of plaster-of-Paris was applied from the toes to the middle of the thigh. The highest temperature recorded was 99.6°, forty-eight hours after the injury. There was no pain after the second day, and the splint was not cut down for two weeks, when the dressing was found soaked with a dried bloody discharge. On removing the gauze-packing the wound was found clean and beginning to granulate. The position of the fragments was excellent. The wound was washed out with hydrogen dioxid and bichlorid solution, 1 : 5000, repacked loosely with iodoform-gauze, and the plaster-splint reapplied. Two weeks later the dressing was again changed. The patient had complained of some pain, and there was found a considerable discharge from the wound of an unhealthy-looking serous character, as well as some redness and edema about the edges. There was no elevation of temperature, and the general health was unimpaired. The wound was irrigated with hydrogen dioxid and bichlorid solution as before. Some infection being suspected, the wound was packed with gauze soaked in bichlorid solution, a wet dressing of the same applied, and the leg put up in a long Volkmann posterior splint. Two days later the dressing was changed, and all signs of inflammation having disappeared the leg was again put up in plaster. Recovery from this point was uninterrupted. The splint was cut down, the dressing changed, and the splint reapplied about every two weeks until the wound healed, which was accomplished in nine weeks from the time of the accident. Union of the fracture was somewhat delayed, but finally became firm. When seen six months after the injury the man was attending to his business, and had complete use of the limb. He still complained of occasional pain, which he described as "rheumatic," and there is at times some edema of the foot, apparently caused by poor circulation.

Case VI was a man, thirty-five years of age, who was run over by a truck. Examination revealed a comminuted fracture at the middle of the right tibia, with a large wound leading directly to the bone, a fracture of the fibula at the same level, and a simple fracture of the femur on the same side, at one inch above its mid-point. The compound fracture of the leg was treated as already described, straps for a Buck's extension being applied over the dressing, and running as high as the point of fracture in the femur. The entire limb from the toes to the groin was put up in plaster-of-Paris. Union in the tibia was delayed, owing to the extensive comminution, but there were at no time any signs of infection in the wound. Five months after the accident the patient was seen, and the usefulness of the limb found completely restored.

Cases VII to XVI, inclusive, were all compound fractures of the tibia, either with or without an accompanying fracture of the fibula. Each was treated as already described, and all escaped suppuration. A practically perfect result was obtained in every case, the usefulness of the limb being restored in periods varying from seven to twelve weeks.

Case XVII was a man, twenty-seven years old, an alcoholic, who, while intoxicated, was run over by a street-car. There was a ragged, contused wound over the inner aspect of the ankle which exposed a fracture of the astragalus. The tissues were much bruised and torn. The wound was treated as usual, the leg and foot being put up in a plaster-splint. On the second day the temperature was 100.5°, and the patient exhibited the early symptoms of delirium tremens. These disappeared under large doses of strychnin and thirty-grain doses of trional, given to induce sleep. He did perfectly well until the tenth day after the accident, when he complained of a feeling of stiffness in the muscles of the lower jaw. The splint was immediately cut down and the wound examined. It looked well, except for some slight sloughing of the contused edges. It was washed out with hydrogen dioxid and bichlorid solution, and redressed. The patient gradually developed a well-marked typical attack of tetanus, dying a week later in a tetanic convulsion. In the meantime the wound was again opened up and washed out with a saturated solution of potassium permanganate, but without any effect on the course of the disease. This case is of especial interest as showing that, while the original efforts at disinfecting the wound were successful in destroying or rendering inactive the pyogenic bacteria, the tetanus-bacilli escaped.

Case XVIII was a woman, sixty-five years of age, who fell down a flight of stairs, receiving numerous contusions and a compound fracture of the right humerus near the elbow-joint. A ragged wound on the posterior aspect of the elbow opened directly into the joint-cavity and revealed a typical T fracture of the lower end of the humerus, with a chipping off of a small fragment of the olecranon process of the ulna. This last was removed, and the fragments of the humerus were wired together, it being otherwise impossible to maintain them in position. The wound was dressed as described, the arm being put up in a plaster splint, the forearm in a position between pronation and supination, and flexed at an angle a little less than 90°. Although warned of the danger, the patient left the hospital the next day, reappearing five days later, unable to give an intelligent account of her movements in the meantime, and with a temperature of 103°. The skin about the wound was reddened, and there was slight edema, but no pus. The wound was washed out with hydrogen dioxid and redressed, the arm being put up in a right-angled tin splint, and rest in bed ordered. The temperature at once fell, and all signs of inflammation promptly disappeared. A week later the arm was again put up in plaster, and recovery was uninterrupted from this point. In six weeks there was firm union, and passive motion was begun. Three months after the injury flexion and extension were nearly complete and she used the arm in washing and household work.

Case XIX was a man, twenty-eight years of age, who was run over by a cart. A ragged, contused wound on the inner aspect of the arm exposed a comminuted fracture of the left humerus opposite the point of insertion of the deltoid muscle. The wound was treated as usual, the deformity being reduced by making traction on the extended forearm. A plaster splint was applied from the fingers to the axilla and running over the point of the shoulder, the arm being at right angles to the body, and the forearm extended on the arm. There was no rise of temperature, and the wound healed readily. Four weeks after the injury the elbow was bent under chloroform and a plaster splint reapplied, with the forearm flexed on the arm at a little less than a right angle. In nine weeks union was firm and passive motion was begun. Three months after the accident the usefulness of the arm was fully restored.

Case XX was a man, fifty years of age, who was run over in the street, receiving a compound fracture of the left humerus. This case is almost an exact counterpart of the last, and was treated in the same way. In eight weeks the union was firm, the wound had healed, and passive motion was begun. Four weeks later the patient returned to work with full use of the arm.

A review of these twenty cases, taken without any attempt at selection, and comprising all the serious compound fractures treated in the hospital during a period of six months, shows that in eighteen (90 per cent.) a practically perfect result was obtained, without pus appearing in the wound at any time. This ought to be sufficient to banish from all minds the idea that in compound fractures suppuration is inevitable. And this is an idea that, even in this age of antiseptics, is surprisingly prevalent outside of the large medical centers.

The study of these cases leads us to the conclusion that the essentials of treatment are:

I. To cleanse thoroughly and disinfect the wound at the earliest possible moment after the injury, and to keep it in an aseptic condition until it is healed.

II. To reduce accurately the deformity and apply a splint that shall hold the bony fragments in proper position, at the same time giving the parts surrounding the wound that perfect rest which contributes in no small degree to rapid healing.

In accomplishing the first of these aims the following points may be emphasized:

1. The thorough disinfection of the hands of the surgeon.
2. The sterilization of all instruments and dressings.
3. The laying open, by free skin-incisions, of all pockets and sinuses in the wounded tissues.
4. The securing of free drainage by leaving the wound open and packing it with gauze.

Finally, it may be remarked that while the foregoing results were obtained in hospital practice, there are in private practice no special difficulties in the way of carrying out the same treatment and obtaining the same results.

THE THOMSONIAN AND BOTANIC MEDICAL SYSTEMS.

By J. BEN NICHOLS, M.D.,
UNITED STATES SOLDIERS' HOME, WASHINGTON, D. C.

The Thomsonian medical system arose in the United States early in the present century, attained considerable prominence and popularity for a few decades, largely under the name of botanic medicine, and is now nearly or quite extinct, with the exception of a slightly modified form known as physiomedicalism, which still survives in a few localities. The prominence and influence which the system in its time attained give it a place in the history of medical sectarianism. The subject seems sufficiently profitable and interesting as a matter of medical history and general medical information to warrant this historic and doctrinal review.

Samuel Thomson, the originator of the system, was born in 1769 in Alstead, a country place in Southwestern New Hampshire. He was brought up in the country, had almost no education whatever, and as he grew into manhood engaged in farming. About 1792 he began to doctor, at first in his own family and then among his neighbors. As years passed he developed his medical notions, and his reputation and practice extended. From about 1806 he engaged in itinerant medical practice, travelling about from town to town in Northern New England. In 1813 he obtained a patent on his system, by virtue of which he claimed sole proprietorship and control of it, and made the "right" to use it a simple article of commerce. Under his management Thomsonism was preëminently a system of family medicine and treatment. He taught that food and medicine are analogous, and, growing side by side in the fields, it is as simple and natural for people to prepare and administer their own medicines in disease as to produce food for hunger. A scheme for doing this and the right to use it was what Thomson had for sale; he charged $20 for each invisible right and a little book of instructions, the purchasers agreeing not to divulge any of the information so obtained, and being organized into the "Friendly Botanic Society."

For many years Thomson travelled about, mostly in New England, selling his right, books, and medicines, and overseeing the operations of local agents. With the latter Thomson was usually at loggerheads, due to his selfishness, avarice, and jealousy. The profits from the sale of his twenty-dollar patent book must have been something handsome; his agent for the Ohio Valley and the South, for instance, in 1827–30 sold 4000 copies, representing a gross return of $80,000. About 1822 Thomson published two books on his system, by which its extension beyond the limits of his personal management was facilitated. These were a *Narrative of the Life and Medical Discoveries of Samuel Thomson, Containing an Account of His System of Practice and the Manner of Curing Disease with Vegetable Medicine upon a Plan Entirely New*, partially unfolding the system; and his *New Guide to Health, or Botanic Family Physician*, which contained his autobiography and a complete presentation of the system. These books had a large circulation, and went through many editions during the next twenty years. In 1841 *The Thomsonian Materia Medica, or Botanic Family Physician*, was published, a larger and more pretentious treatise, nominally by Samuel Thomson, but really written by his son John. Samuel Thomson died at Boston in 1843.

From the testimony of contemporaries, and even followers, it appears, as his autobiography indeed shows, that Thomson was an ignorant, illiterate, narrow man, high-handed with others, and of some financial shrewdness. He had practically no education whatever, least of all in medicine; he never attended a medical school or studied under a preceptor. His medical knowledge consisted in the notions picked up by a narrow and ignorant man within the small field of observation of a country neighborhood. He says, for instance, that nearly all his instruction in obstetrics consisted in a twenty-minute conversation with a midwife. One would suppose that such an utter lack of education would have entirely discredited all Thomson's pretensions to medical knowledge and authority.

The Thomsonian pathologic and therapeutic doctrines, as promulgated by their founder and held by his stricter followers, were essentially as follows:

Heat is life and cold is death. Life depends on heat; food and medicine are the fuel of heat, and therefore of life. The process of digestion causes the consumption of food, and thus supports the heat and vitality of the body. The stomach, therefore, is the organ upon whose proper action depends almost entirely the maintenance of heat and health. When the food is not digested properly the production of heat diminishes, the vital powers are depressed, and this constitutes disease. The main indication in the treatment of disease is, accordingly, the clearing out of the stomach and its restoration to proper action; this Thomsonism accomplished by violent emetics.

Heat being the basis of life, fever is a friend and cold an enemy to health. Consequently, from the Thomsonian standpoint, antiphlogistic and antipyretic methods of reducing fever—by bleeding, purgatives, cardiac sedatives, application of cold, etc. —were unnatural, inefficacious, and injurious. All fevers are of the same essential nature, consisting of a decrease of internal and disproportionate increase of external heat, a struggle between the cold and the heat. One of the chief indications of Thomsonian treatment was, accordingly, to promote the fever, or heat, and decrease the cold, for which steam baths and capsicum were the principal agents employed.

The influence of torpidity of the excretory functions, especially of the perspiration, in causing disease was recognized. That all diseases are of essentially the same nature was a doctrine which justified the practice of treating all diseases in essentially the same way.

Thomson had other notions concerning "canker," the vital power, respiration, medieval ideas of the elements (earth, air, fire, water) composing the body, etc., which are beyond ordinary comprehension or have no practical medical bearing.

The Thomsonian therapeutic agencies consisted of a few drugs, mostly arranged in six classes and designated by Thomson (but not so much by his followers) by numbers rather than by name, steam baths, and injections.

Thomson's "No. 1" was emetic medicine. Violent and repeated emesis was practised in nearly all cases of disease, and to this treatment the most beneficial results were ascribed. For this purpose lobelia, the main drug of Thomsonism, was employed in tremendous doses, as high as one-half ounce of the seeds. In the face of repeated fatal cases of poisoning by the drug, and of numerous legal trials to which many of them were subjected for deaths caused by its use in their practice, the Thomsonians insisted that lobelia was a perfectly harmless, innocuous medicine, not under any circumstances poisonous; and they endeavored to explain away the fatalities that occurred under its use, and denounced the assertions of its poisonous nature as malicious slanders. Of this point the following remarkable passage from *Wilkinson's Botanico-medical Practice* (1845), relating to the attitude and opinions of regular physicians concerning lobelia, is a characteristic illustration:

> "Every particle of honesty, goodness, benevolence, and every other Christian virtue and gentlemanly principle was wholly disregarded and swallowed up in their determined, combined, formidable, and unceasing opposition to this innocent plant. Every mean, low, base, insignificant, wicked, ungentlemanly, unfair, Heaven-daring, principle-disgusting, and soul-revolting measure was eagerly and promptly made use of to suppress the expanding and deserved fame that lobelia was constantly acquiring."

"No. 2" was stimulants—capsicum and the like. "No. 3" consisted of astringents, or "canker medicine." "No. 4" was "bitters, to correct the bile and restore digestion." "No. 5" was peach-meats and cherrystones, "syrup for the dysentery, to strengthen the stomach and bowels, and restore weak patients." "No. 6," myrrh, turpentine, and camphor, was "rheumatic drops." Other preparations were nerve-powder, composition, cough-powder, cancer plaster, salve, etc.

Steam baths were one of the main features of Thomsonian treatment; they were universally used, and the highest importance was laid upon their operation.

"Courses of medicine" constituted a prominent method of treatment; these were used as a routine measure in most cases of disease. A course of medicine usually consisted of, first, a steam bath; next, profuse emesis with lobelia; third, an injection to open the bowels; fourth, another steam bath. These courses were repeated indefinitely; they were employed indiscriminately, and extravagant claims were made for their efficacy.

Thomsonism made lofty claims of using only innocuous and gentle medicines, and vigorously denounced bleeding and the use of alleged harsh drugs, like opium, mercury, arsenic, antimony, niter, and other mineral medicines. It styled itself a botanic system, and attempted to create prejudice against the employment of mineral drugs, and cast a slur on regular medicine by calling it the mineral school and charging it with a predilection for using injurious treatment.

Thomsonism first attained popular strength in New England under Thomson's personal management, and was sustained in that region largely by his personal efforts. It achieved a more extensive and more enduring development elsewhere through his agents and the circulation of his books, apart from his personal influence, and by 1830 became widely disseminated through the Atlantic States and Ohio Valley. Thomson held the practice and the followers of his system well under his proprietary control until about 1830. Differences then appeared among his followers, and an element arose which was disposed to renounce his doctrinal and proprietary authority. Thenceforth Thomson's personal influence declined greatly, although the sale of the "right" continued at least as late as his death, in 1843. In its fullest development Thomsonism thus became divided into well-marked elements, differing more in ethics, name, and organization than in principles or practice, namely, (1) strict Thomsonism; (2) the more liberal section, commonly known as the botanic or botanico-medical system, from which developed (3) physio-medicalism, the only form of Thomsonism which continues in existence in America, to any extent at least, at the present time.

The strict Thomsonians, while slightly modifying his methods, professed to follow Thomson's teachings closely, and denounced the innovations and "improvements" of the botanics.

The main body of the adherents of the system, however, rejected Thomson's claims to a monopoly of it, and broke from his control. They generally styled their system the botanic or botanico-medical system; also (later) the reform medical system, and employed these names rather more commonly than the original designation, Thomsonian. They established the schools and journals and produced most of the literature of the system. The difference between their opinions and practice and those of the so-called strict Thomsonians was exceedingly slight; yet the refinements and innovations which they introduced were vigorously denounced by the latter. The main difference lay in organization and ethical methods, in the fact that original Thomsonism was a proprietary system for family and lay practice. Thomson bitterly opposed this element, since it injured his vanity, prestige, and profits.

This more respectable form of Thomsonism arose about 1830, concurrently with eclecticism, with which it was for a time quite closely associated, and was at its height in the United States for two or three decades following. Its greatest strength was in Ohio (also the headquarters of physio-medicalism and eclecticism), Massachusetts, New York, Pennsylvania, Georgia, and the adjacent sections, extending also into Canada. Over this wide territory at the time of its prevalence the system was very extensively diffused, and had quite a strong hold upon the people, especially and mostly in the country and among the lower classes. Botanic medicine had some organization for a time, in State societies, etc., but never secured much legal recognition. Considerable literature devoted to the system appeared, of which empiricism and illiteracy were prominent characteristics. The periodicals of the system were quite numerous, but mostly ephemeral. Of the five or six schools established to teach the system, all except two were short-lived, or after from two to four years of existence adopted eclecticism; these two were the Botanico-medical College of Ohio (the first botanic school), organized in 1839, which became the chief physio-medical educational institution, and the Southern Botanico-medical College of Georgia, organized soon after the preceding, which continued under various organizations and names, and finally merged into an eclectic school.

Botanic medicine was introduced into England about 1848 by the teachings of A. I. Coffin, after whom his followers received the ominously appropriate name of Coffinites. In that country it rapidly attained a large following and very many irregular practitioners or "poisoners," and achieved much notoriety from the frequent cases of fatal lobelia-poisoning, and convictions for manslaughter ensuing. The system survived there longer than in the United States, and probably still lingers to some extent.

By about 1860 botanic and Thomsonian medicine in the United States had lost its schools, journals, literary activity, and many of its adherents, and was on the decline. Much of its strength went over into eclecticism. Its last stronghold was Macon, Georgia, where a Thomsonian journal and college continued as late as or later than 1860. The system has become virtually extinct in its original form, with few if any genuine stragglers still surviving from the past.

Physio-medicalism arose among the botanics about 1840, under the teachings of Alva Curtis; this has continued in existence in some localities under a distinct organization and name.

Concerning the merits of the Thomsonian system little need be said. Thomson's commercial motives and methods of promulgating his practice were simply one with the many quack and patent-medicine enterprises now in operation, and his system would deserve no more notice than any of these except for its influence and bearings upon medical sectarianism in the United States as a matter of medical history. The Thomsonian theories were the crude, illogical, and frequently absurd notions of an absolutely uneducated man, whose entire observation and experience had been limited to the narrow field of a remote country neighborhood, and who was largely actuated by mercenary motives. The partial degree of truth in some of Thomson's ideas was exalted by narrow ignorance and enthusiasm to an exaggerated importance, so that the multitude of other and more important medical facts were lost sight of. The fact that theories and methods such as these, and coming from such a source, should have received general and wide acceptance is an instance of the narrowness which the exaltation of one idea always produces and a commentary upon the gullibility and pervertibility of the human mind. The final extinction of Thomsonism throughout the extensive region where once it was a familiar household word, after undergoing the fullest trial by the world, was simply the inevitable fate of error.

CASES OF DIPHTHERIA TREATED WITH AND WITHOUT THE ANTITOXIN.

BY ROMULUS A. FOSTER, M.D.,
OF WASHINGTON, D. C.,

From the tabulated statements appended it appears:

1. That of 2740 cases of diphtheria—selected and unselected (and which included those that required tracheotomy and intubation)—treated with the antitoxin, only 509 died, or a mortality of 18.54 per cent.

2. That of 4445 cases, which also included those that required tracheotomy and intubation, not treated with the antitoxin, 2017 died, or a mortality of 45.36 per cent.

3. That all the cases recovered in which the antitoxin-treatment was begun on the first day of the disease; that 2.83 per cent. of the cases died in which it was begun on the second day; that 9.99 per cent. of the cases died in which it was begun on the third day; that 20 per cent. of the cases died in which it was begun on the fourth day; that 33.33 per cent. of the cases died in which it was begun on the fifth day; and that 41.38 per cent. of the cases died in which it was begun after the fifth day.

The average quantity of serum administered, hypodermically, was from 1 to 10 cubic centimeters (15 minims to 2½ fluidrams) in mild cases, and from 10 to 25 cubic centimeters (2½ to 6¼ fluidrams) in severe cases.

The injection was made either in the gluteal region or in the back, below or between the shoulder-blades; and if the patient was not better the next day another was given him. The second dose was similar to the first or somewhat smaller. Aronson says that one should not hesitate to give a dose of 50 cubic centimeters (12½ fluidrams) in malignant cases, and Seitz suggests intervals of ten hours between doses. The serum of the immunized horse, Roux claims, is wholly uninjurious to man, even in large doses. Injected under the skin, it is immediately absorbed, without giving rise to any local irritation.

In regard to the employment of the serum as a prophylactic, the following is reported by Hilbert: Of ten children treated with Behring's normal serum, only four contracted diphtheria; of eight treated with the sixfold strength of Aronson's serum, not one contracted the disease; of eighteen treated with the thirtyfold strength of the same serum, two contracted the disease; and of 28 treated with the sixtyfold strength of Behring's antitoxin, one contracted the disease. In the inoculated children who contracted diphtheria the disease pursued a mild

course and terminated favorably. It is also reported that of seventy-two brothers and sisters of affected children to whom a small dose was given, only eight were attacked with diphtheria; and that of thirty-eight brothers and sisters of patients to whom a larger dose was given, all escaped. Those who received the antitoxin were rendered immune to the disease in a very short time, but it was found that the immunity was not permanent; that it disappeared after a few day or weeks. For preventive inoculation 150 antitoxic units are now recommended; that is, from 2 to 3 c.c. (30 to 45 minims). The serum cured all the cases of diphtheria associated with staphylococci, but only 65.72 per cent. of those associated with streptococci. The latter were found to be especially dangerous.

It should be borne in mind that the serum has a destructive effect on the red blood-corpuscles, and that the following secondary effects have been observed in a few of the cases treated with it: Erythema multiforme; an urticarious eruption associated with malaise, glandular enlargement, and paresthesia; pains in knee-joints, ankle-joints, and elbow-joints, and swollen and reddened ankle-joints; a purpuric condition. The secondary effects, however, did not last longer than several weeks.

Although some of the cases which showed a decided improvement in the first two days became gradually worse, and died later of nephritis and cardiac paralysis, it is claimed that these complications in diphtheria are rendered less frequent by the serum or antitoxin treatment.

BACTERIOLOGIC EXAMINATION IN THE DIAGNOSIS OF DIPHTHERIA.[1]

BY WILLIAM G. BISSELL, M.D.,
BACTERIOLOGIST, DEPARTMENT OF HEALTH, BUFFALO, N. Y.

A GREAT deal has been said on the laboratory-technique and the value of bacteriologic examination in the diagnosis of diphtheria, yet the subject is of sufficient interest and importance to warrant a further explanation of the methods used in culture-examinations. It would seem unnecessary to go into the history of the organism further than to state that it was discovered by Klebs in 1883, and first artificially cultivated by Loeffler in the year following. The germ is generally known as the Klebs-Loeffler diphtheria-bacillus, and it has been fully proved to be the etiologic factor in the production of the disease.

It is generally admitted by all clinicians of experience that it is often impossible to make an accurate diagnosis of diphtheria, either from the clinical history, the anatomic lesion, or from both. There are no constant differences that separate the simple non-contagious forms of inflammation from the diphtheric type, and it is in but a very small proportion of cases that an early and reliable diagnosis can be reached from any data obtainable. This was conclusively demonstrated in the examination of the cases of suspected diphtheria under treatment at the Willard Parker Hospital in New York, where the diagnoses were made by department diagnosticians and confirmed by the best medical talent. Subsequent bacteriologic examination in these cases revealed that from 30 to 50 per cent. were not diphtheria, but maladies of non-infectious character. Appreciate sending a case of follicular tonsillitis to a hospital and having it placed in a ward with diphtheric patients! This person, with a reduced vitality, is exposed to one of the most dreaded diseases when suffering from a malady to which hardly one in twenty-five succumbs.

a. It is in just such cases that an early bacteriologic examination is of the greatest sanitary importance.

Furthermore, it has been proved that in cases in which the Klebs-Loeffler bacillus has been found virulent diphtheria has been transmitted to others, whereas the person carrying the contagion was hardly in a condition to be called ill.

---

[1] Paper read before the semi-annual meeting of the Erie County Medical Society, January 8, 1895.

b. It is the systematic bacteriologic examination of such cases that plays a most important part in the advancement of preventive medicine.

Again it has been fully demonstrated that the bacillus of diphtheria remains a varied length of time in the throats of persons convalescing from the disease, even after the disappearance of all membrane and constitutional symptoms. Such persons, if allowed to go at large, are a constant source of infection, transmitting the disease to others, and in this way increasing the prevalence of the malady.

c. It is from the bacteriologic examination in such cases that the greatest practical benefits can be derived.

Early in January, 1893, through the energetic efforts of Dr. Herman M. Biggs, of New York, a communication was addressed to the Health Board of that city, recommending systematic bacteriologic examination for the diagnosis of diphtheria. After some unavoidable delay, bacteriologists were appointed in accordance with the recommendation, with such assistance as was necessary thoroughly to carry on the work. From the time of the inauguration of this scheme those in charge had very little doubt of its ultimate success, but there were a few who doubted its practical efficiency. Several depots were established in various parts of the city, where culture-sets could be procured, and every step was taken to increase the facilities for early examination. Circulars were printed and sent to physicians, asking their hearty co-operation in the movement, and explaining the great necessity for such examinations. During the first few weeks the cases examined were comparatively small, but they have continually increased in number until at the present time the practice is universal.

In order to make clear the methods used in such examination it will be necessary to describe briefly the materials required. The culture-medium most suited for this work is a preparation of blood-serum after the formula of Loeffler. Pure serum is obtained by allowing the freshly drawn blood of a young sheep or ox, contained in a wide-mouthed sterile jar, to remain twenty-four hours in an ice-chest. By that time the fluid part of the blood has separated from the solid portion, and is easily drawn off by means of a pipet. This serum is mixed in proportions of three to one of a 50 per cent. neutral sterile beef-infusion, containing 1 per cent. peptone, 1 per cent. dextrose, and ½ per cent. of common salt. This mixture is then poured into small sterile tubes (putting about 2 c.c. in each tube) and carefully sterilized in a blood-serum sterilizer, at a temperature of about 160° F. The tube is put at an angle during the process of sterilization so that after the coagulation of the blood-serum mixture one will have the greatest possible surface for the planting of bacteria. After these tubes have been rendered absolutely sterile they are ready for use. A sterilized tube containing a swab goes with each culture-tube, and these tubes compose the so-called culture-set.

How to make the primary inoculation is explained by a printed slip accompanying each culture-set. The slip, as supplied by the Department of Health in this city, reads as follows:

DIRECTIONS FOR MAKING CULTURES IN CASES OF SUSPECTED DIPHTHERIA.

The patient should be placed in a good light, and, if a child, properly held. In cases where it is possible to get a good view of the throat, depress the tongue and rub the cotton swab gently, but freely, against any visible exudate.

In other cases, including those in which the exudate is confined to the larynx, avoiding the tongue, pass the swab far back, and rub it freely against the mucous membrane of the pharnyx and tonsils. Without laying the swab down, withdraw the cotton plug from the culture-tube, insert the swab, and rub that portion of it which has touched the exudate gently but thoroughly back and forth over all the surface of the blood-serum. Do not push the swab into the blood-serum, nor break the surface in any way. Then replace the swab in its own tube, plug both tubes with the cotton plugs, and return the culture-set at once to the Health Department.

A report will be given by telephone the following morning, or can be obtained after 12 noon.

As soon as the tubes arrive at the department, that containing the inoculated blood-serum is placed in the incubator at a temperature of 36° C., and allowed to remain until sufficient growth appears to permit of examination. This requires a period of from twelve to twenty-four hours. After the proper time has elapsed a cover-glass preparation is made from the growth in the tube, stained with alkaline methylene-blue solution, and mounted in the usual way with Canada balsam. On microscopic examination of such a preparation with a 1-12 oil-immersion lens—if it is from a case of true diphtheria—the following picture will present itself: A large number of rod-shaped organisms stained blue, varying somewhat in length, about the same size as the tubercle-bacillus, but twice as thick, frequently clubbed and spindle-shaped, and almost invariably irregularly stained, presenting heavily stained segments in a lightly stained background. This is the bacillus of diphtheria.

It is claimed by some that the recognition of the bacillus is extremely difficult, owing to its resemblance to the germ described by Hoffman. It is the general opinion, however, that with thorough examination of the bacterial growth, as described, which has been carefully inoculated according to the rules given, and kept at the temperature of the body, the microscopic examination can be, without doubt, relied upon. Of course, the majority of tubes sent in for examination will not reveal any bacilli, containing simply the common cocci found in the throat. In such cases a positive diagnosis is extremely easy. It was thought at one time that the size of the germ had to do with its virulence, but this is now generally conceded not to be the fact.

Much has been said by some authors as to an organism that by its culture-peculiarities and microscopic appearance is identical with the Loeffler germ, yet does not possess pathogenic properties when injected into susceptible animals. The name given to the organism is the "pseudo-diphtheric bacillus," and, as expressed by Abbott and other prominent workers in this field, it seems certainly to be a misnomer, for it is most possible and probable that this organism is none other than the true diphtheric germ, attenuated in virulence, or, as circumstances have rendered it, a non-virulent diphtheric bacillus.

It would appear to be far better to term "pseudo-diphtheric" those organisms that are enough like the true bacillus to attract attention, yet are distinguishable from it by certain morphologic and cultural peculiarities aside from the question of virulence.

It is a well-known fact that many pathogenic organisms, conspicuous among them being the micrococcus of sputum-septicemia and the so-called hemorrhagic septicemic group, undergo marked variations in the degree of their pathogenic properties, yet such organisms are not designated as "pseudo," but simply the organisms themselves, having become attenuated in virulence.

Loeffler, himself, found the Klebs-Loeffler bacillus present in the case of a perfectly healthy child. Was the germ found virulent? Was it the germ of true diphtheria, or was it the resistance on the part of the patient, the healthy secretions and conditions of the mucous membrane, which lessened its virulence in this particular case? It seems most reasonable that it was the latter. If not, why is it that frequently, on examination of cultures made from the throats of persons taking care of diphtheric patients, one finds the germ present, and yet these persons present no constitutional disturbance. It is because the proper conditions are not present for the development of the disease, whereas others receiving the infection from an attendant might contract the disease in its most deadly form.

There happens in a certain number of cases which clinically are diphtheria, that the first inoculation will fail to show any diphtheria-bacilli. These cases, however, are exceptional, and it is not usually the fault of the bacteriologist that such is the case, because there are certain factors that should be taken into consideration:

1. The inoculation may have been made at so late a period in the disease that it is possible that the diphtheria-bacilli, though now absent, were present at an earlier time.

2. The growth on the culture-medium may be so scanty that it is probable that the inoculation was not properly made, or that some antiseptic had been applied to the throat shortly before obtaining the material for inoculating the tube, sufficient of the antiseptic remaining to prevent growth on the serum.

3. The culture-medium may be badly contaminated and a positive recognition of any one organism be impossible.

4. The serum in the tube may have become too dry before the inoculation to permit of the growth of the diphtheria-bacilli.

In all these cases a second inoculation should be requested by the bacteriologist before giving a definite opinion as to the diagnosis.

Of the primary cultures examined at the Health Department in this city since the 1st of March, 1894, sixty-five were found to contain the Klebs-Loeffler bacillus and ninety-nine were found not to contain that organism. This makes a showing that about 39 per cent. of the cases were true diphtheria.

One case examined during that time of peculiar interest was that in the practice of Dr. Eugene Smith, of this city. Dr. Smith on the 18th of December, 1894, inoculated a tube from the pharynx of a child suffering with a malady characterized by great toxic disturbance, and, as he thought, possibly diphtheria. The tube was sent immediately to the Health Department and placed in the incubator. After twenty-four hours there was no apparent growth on the blood-serum, and a second inoculation was requested. The result of the second inoculation was like that of the first, there being no apparent growth after the twenty-four hours in the incubator. On microscopic examination of the swab it was found to contain a considerable amount of a glistening whitish exudate. Two side-mountings were made of this exudate, one being stained with methylene-blue, and the other by Gram's method. On microscopic examination of these slides there was found to be present an organism having a distinct encapsulation and resembling morphologically the organism described by Fraenkel as being the etiologic factor in the production of pneumonia. The result of the examination was communicated to Dr. Smith. That night the child developed characteristic pneumonic symptoms, and is now convalescing from the disease. The primarily inoculated tubes were left in the incubator, and after the fifth day showed a growth consisting of several small clusters of isolated fine points, growing closely side by side, like those of the diplococcus of pneumonia. Some of the exudate from the swab was inoculated into several mice, and the animals died invariably inside of forty-eight hours of an acute septicemia.

All these points tend to show that the organisms found correspond with the Fraenkel germ, and it is of interest in that it fully explained why development did not occur on the blood-serum during the first twenty-four hours.

As to the points, in conclusion, which may be definitely stated, in relation to the bacteriologic examination in the diagnosis of diphtheria, there are the following:

1. A positive diagnosis of diphtheria can be reached in the majority of all suspicious cases by careful examining of the primary culture, inoculated as described, inside of twenty-four hours.

2. In cases in which the bacillus is not found there is little chance of infection.

3. In those cases in which the diphtheria-bacilli are found the cases should not be considered free from infective powers until subsequent bacteriologic examinations fail to reveal the organism.

Note.—During the discussion of this paper by various members of the Society an elderly and trusted physician brought up the old-time question as to whether diphtheria is primarily a local or a constitutional disease. He stated that he "believed that primarily it was always a constitutional disease, with perhaps sometimes coincident local manifestations," *i. e.*, it was always the result of etiologic factors from within the body, and not a primary local affection.

With others I strongly contested this idea, and a heated argument ensued. Bacteriologists and men of experience should discuss this question in the current literature.

186 Allen Street.

LOCAL OR GENERAL TREATMENT IN GONORRHEA?

By J. HENRY C. SIMES, M.D.,
of Philadelphia, Pa.

Those who have given any attention to the treatment of gonorrhea cannot have failed to notice that during the past year or two there has been a tendency for surgeons to advocate the internal treatment and to discard the local treatment. This has impressed me as being very singular, when taken in connection with the views advocated as to the nature of the affection, and I am not able to reconcile the one with the other. All, with very few exceptions, are now advocates of the theory that the affection is of a local nature, having for its etiologic factor a local irritant. Such being the case, one naturally is astonished to find that the treatment of the lesion has taken a direction contrary to that which the pathology of the disease would seem to indicate. That is to say, does it not seem more reasonable—indeed, is it not one of the first principles of treatment, to remove the cause, and to accomplish this as rapidly as possible? Therefore, if it is admitted that the lesion is not only local, but also dependent upon a local cause, and the location is amenable to local treatment, is it justifiable to neglect the local and adopt the internal or general treatment?

Before answering this question it is not to be forgotten that gonorrhea, like all the acute contagious diseases, has a certain course to run, and tends to recovery, but also, like this class of affections, it is more or less modified by treatment, which may lessen its duration and prevent complications; therefore, the recovery of the patient is not always to be credited to the method of treatment; rather in many cases the disease is cured in spite of the treatment.

As to the employment of internal treatment in gonorrhea, and the condemnation of local treatment, I find that, in the majority of cases, it is stated that the latter method is more likely to occasion some complication, and in this way lengthen the duration of the attack, while the former is said to be free from this objection. To say that any method of treatment in a case of gonorrhea will or will not be followed by some complication would, indeed, be very foolish, as there is no disease in which the prognosis is so very uncertain, not so much on account of the method of treatment adopted, but more on account of the treatment the patient himself has, contrary to advice, adopted. This aside, however, it remains to be asked, Does the local treatment, the method by injection, in gonorrhea tend to occasion complications? My experience has most certainly taught me that it does not; but its abuse may, and undoubtedly will give rise to complications the same as the abuse of internal remedies will also cause complications. The mucous membrane lining the urethra is a very delicate structure, and it is to be treated with much care, especially when in an inflamed condition; therefore, the object should be to allay all irritation, and make no application that may possibly increase its irritability. If this is always remembered when treating a case of gonorrhea, there may be no anxiety as to the method of treatment giving origin to any complication. Again, it is important to remember that the strength of the injection is not always to be the same for all cases, nor the same for all stages of the attack, nor is the same medicinal remedy admissible in all cases, or during all stages of the same case, but must vary according to the judgment of the surgeon.

Those who advocate internal treatment in cases of gonorrhea very justly claim that this method is not in truth a general method of treatment, but a local one. This must be admitted; it is local to the extent of the medication being secreted by the kidneys, and of its being mixed with the urine. Thus the medicated urine is a local application to the affected part of the urethra. Notwithstanding this fact, is it not a very roundabout way to accomplish what can be done in a much more satisfactory manner by a direct application to the diseased part? If a somewhat analogous treatment of the same affection, when it attacks another organ of the body, were adopted by the surgeon, the result would be most disastrous. I refer to the treatment of a case of gonorrheal ophthalmia, in whch the neglect to adopt a local method of treatment would certainly not result in adding to the reputation of the surgeon, and the uncontrolled progress of the disease would most probably occasion destruction of the organ. We have the same disease attacking similar anatomic structures, viz.: gonorrhea and a mucous membrane, and experience has taught in one that the best results are obtained by local therapeutics, while in the other there remains a doubt. To my mind such a doubt ought not to exist. If the local treatment of a case of gonorrheal ophthalmia is found to control the disease and prevent destruction of the organ, and to do this more quickly and more certainly than any other method, why is not the same method applicable to the same disease when it attacks the mucous membrane of the urethra? That the anatomic relations of the two organs are not analogous is undoubtedly true, but their anatomic structure is very nearly analogous, and a method of treatment that is admitted to be most efficient in one should be, and for myself is, applicable for the other.

The internal treatment of gonorrhea, it must be admitted, has a controlling and beneficial effect over the disease. It is a method to be recommended, and one that will show good results; but the local method by injections I have found superior in its results, and it is certainly more reasonable when the nature of the lesion is considered. Many surgeons have come to the conclusion that both methods are to be recommended, and that a combination of the two is the most desirable method of treatment. There is, of course, no objection to adopting this plan, except, I think, that one thus uses unnecessary medication, which is always to be avoided, and he may in very many cases occasion the patient considerable discomfort by the administration of internal remedies, as the drugs that are given in these cases are, as a class, most disagreeable to the taste, and frequently disagree with the digestive organs. Further, and most important, is the fact that the effect upon the disease by this double method of therapeutics has not, in my experience, been in any way of advantage; the duration of the attack has not been shortened and a modification of the symptoms has not been noticed.

It is to be understood that in advocating the local treatment of gonorrhea I do not propose to exclude entirely internal medication. Laxatives, diuretics, alkalies, all have their place, and are very valuable adjuncts; but it is to the employment of the so-called specifics, and the neglect to use proper local applications, that objection is made.

2033 CHESTNUT STREET.

CLINICAL MEMORANDA.

A CASE OF LATE SYPHILIS SHOWING UNUSUAL LESIONS OF THE SKIN.

BY J. ABBOTT CANTRELL, M.D.,
OF PHILADELPHIA, PA.;
PROFESSOR OF DISEASES OF THE SKIN IN THE PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE, DERMATOLOGIST TO THE PHILADELPHIA HOSPITAL AND TO THE SOUTHERN DISPENSARY.

THE appearance of syphilis of the skin, especially when this occurs in the later stages of the disease, the so-called tertiary period, is likely to be manifested so often in very peculiar or even grotesque forms that it is just as likely to resemble some other disease of the skin as the one that has been the real cause of its appearance, and so much does this affection vary that I believe the record of such a case will be appreciated.

The patient, a female, forty years of age, presented herself for treatment at my dispensary service, at the Philadelphia Polyclinic, on the 27th day of March, 1894. She stated that the eruption had existed for the previous seven years, and that it gave her no trouble other than by its appearance. Her family history, as well as her own personal history, seemed to be very fair, and she, furthermore, did not remember ever having had the initial lesion of the disease. The woman was married at the age of twenty-three years, and is the mother of three living and healthy children, all of whom have remained in good health to the present day. Their ages are fourteen, twelve, and nine years respectively. She furthermore affirmed that she had never miscarried, and that the previous births were all natural in delivery, and that she had had no trouble after the births.

The lesions, nine in number, were situated on the extensor surface of the right forearm, and scattered at irregular intervals between the elbow and three inches above the wrist. At the examination the arm was placed with the elbow in the patient's left hand, and the hand of the affected arm at the right shoulder. The first lesion to be described was three inches from the wrist, and was situated with the median line of the forearm running through its center, the lesion extending to within about three-quarters of an inch of either border of the forearm, measuring in itself from one end to the other about one-and-one-half inches, and was shaped like a sickle, the blade being toward the radial side of the forearm, and about one-and-one-half inches long on the curve of its upper border, and from one-eighth to one-quarter of an inch wide. The "handle" was on the ulnar side, and about three-quarters of an inch long, and from one-quarter to three-eighths of an inch in width, taking a downward course toward the inner border of the forearm. At the highest point of the curved portion a fissure ran directly across the lesion, from which a slight discharge of pus was noticeable; the borders of the fissure were irregular.

The second lesion was directly below the first, with about one inch of healthy skin intervening. It was irregularly crescent-shaped; measuring from the highest point to the lowest, it was about one inch in length, and one-eighth inch in width. Its lower half comprised the larger portion, being three-eighths of an inch in width and one-half inch in length across the forearm. From the ulnar side of this lower portion it took an upward course, curving around toward the radial side for a distance of three-quarters of an inch, and was from one-eighth to five-sixteenths of an inch in breadth.

The third lesion was circinate in character, and was diseased throughout, being one-half inch in diameter. It was located on the radial side of the forearm, and about one-half an inch from the median line, and one inch from the outer border of the forearm.

The fourth lesion was parallel with the third, and was the largest and most irregularly shaped of all. It began at a point marking the radial side of the forearm and about five inches from the elbow, running diametrically toward the wrist for about three-eighths of an inch, and being from one-sixteenth to about one-eighth of an inch wide. At this point it widened out and ran horizontally across the forearm for about one-and-five-eighths of an inch, being three-eighths of an inch wide at the beginning of the latter portion (at which point was situated a large tubercle, fissured horizontally) and abruptly diminishing in breadth to from one-eighth to one-quarter inch for its entire remaining length. At the point ending the described portion, which was one-quarter inch from the border of the forearm, the lesion extended obliquely downward and inward toward the median line of the forearm for a length of one-and-one-eighth of an inch, then turned upward and pursued its course obliquely toward the median line for five-eighths of an inch to within one-half inch of its beginning point. The tissue was seemingly healthy and almost enclosed within the described lesion.

The fifth lesion, which was pear-shaped, and lying horizontally, with the apex toward the median line, was two inches below the third lesion and three-quarters of an inch from the median line. It consisted of two tubercles, one five-eighths of an inch in diameter, ovoid in shape, and one one-quarter of an inch in diameter and circinate; they were joined together, the smaller one being toward the median line.

The sixth lesion was one-quarter inch from the head of the ulna, and the same distance from the outer border of the forearm, its lower edge being parallel with the center of the head of the ulnar, and somewhat semicircular in shape. The point nearest the ulna consisted of one large tubercle, ovoid in form, and about three-eighths of an inch long. From the lower part of this tubercle it curved outward, upward, and inward for a distance of about one inch, forming the remainder of the semi-circle and being one-eighth of an inch in width and quite irregular in form.

The seventh, eighth, and ninth lesions were on the ulnar side of the forearm and slightly above the elbow, and one-quarter of an inch from the outer side. They were discrete, although the lesion nearest the inner side of the arm was apparently made up of two lesions that had coalesced. These three lesions were each in itself a tubercle varying from one-eighth to one-quarter of an inch in diameter.

PROLAPSE OF THE LARYNGEAL VENTRICLE.[1]

By WILLIAM S. JONES, M.D.,
of Camden, N. J.;
Chief of Laryngological Department of the Jefferson Medical College Hospital.

The orifices of the ventricle of the larynx are situated between the ventricular bands and the vocal bands, and extend nearly the whole length of the latter. The sac of the ventricle extends upward between the ventricular band and the thyroid cartilage. Its depth varies greatly in different persons. The position of the ventricle is such that there is only a very little strain upon it, even in violent coughing, and probably a person, to have a prolapse from any cause, would have to be in a weakened or neurotic condition producing a relaxation of the muscles and mucous membrane of the larynx.

Mr. R. S., aged thirty-five years, consulted me regarding an impairment of his voice, of four months' duration. On inquiry I found that his family history was not very good, one brother having died of lung-trouble, the family generally being neurotic and the patient particularly so. No other constitutional or acquired disease was manifest. As to the cause of his dysphonia, I found that while attending a game of ball, at a critical point in the game, his favorites gaining an advantage, he arose from his seat in an excited condition and shouted at the very top of his voice. In a few minutes this yell was repeated. At once he noticed a slight impairment of his voice. This was due to a congestion of the vocal bands, for in a few minutes his voice was in a normal condition. In about two weeks from this time he again noticed a slight hoarseness, and as time advanced his dysphonia gradually increased. On examining the larynx I found a large mass, light red in color, situated just above the vocal band of the left side and resting on it. At the posterior and inferior portion of this mass there was noticed a very tenacious piece of mucus, held in position by the pressure of this mass on the band. This was removed. Never having seen an obstruction of this kind, I was in great doubt as to the diagnosis. The only symptom was dysphonia. Here was a large mass unilateral in location, and without surrounding inflammation or infiltration, and free from ulceration. So the idea of it being syphilitic or tuberculous was discarded. The color and smooth surface excluded angioma and papilloma. The broad base was against the theory of myxoma. Its position, shape, and color did not point to malignancy. It was only after several examinations that I concluded that this could only be a prolapse of the laryngeal ventricle.

In looking up the literature on this subject (of which there is nothing definite), among the few cases I find one reported by Prof. J. Solis-Cohen, and in consultation he confirmed the diagnosis.

---

[1] Read before the Camden District Medical Society, November 13, 1894.

Now, why was the dysphonia so long in following the cause, if the cause was his hallooing at the game of ball? The ventricle is held in position by the thryoarytenoid muscle assisted by the attachment of the connective tissue. If its connection with this muscle was severed during a violent strain, the only remaining support would be the attachment of the connective tissue, which would gradually give way with a continued use of the voice until there was a complete prolapse. This would account for the impairment of the voice occurring some time after the cause, also for the increasing dysphonia.

Knowing the cause of this trouble, what is the best treatment? If the ventricle would remain in its normal position, replacement would be the proper procedure. But the condition of its former attachments would be such after four months of displacement that, if reduced, there would be no support to keep it in its normal position. In fact, I have replaced this mass a great many times, only to find that it would return as soon as pressure was removed. The only thing that will restore the voice seems, therefore, to be the removal of the obstruction. This can be done in several ways. The quickest would be by thyrotomy. This the patient objects to. Continued applications of caustics would remove it. The snare might be used in some cases. The cutting laryngeal forceps would also answer.

The treatment I adopted was the electric cautery. I used an electrode made especially for this case, with a shield on the left side to protect the ventricular band. This electrode was placed on the mass at a dark-red heat, and was held there by a slight pressure usually until the patient gagged. This was repeated several times at each visit, under the use of cocain. At first a 10 per cent. solution was used; but this did not have the desired effect, so a 20 per cent. solution was used, which gave the patient perfect control of the larynx. The man's voice now is almost normal. His aphonia has gradually disappeared, and only when he sings is there a slight impairment of the voice.

201 BROADWAY.

A CASE OF DIPHTHERIA TREATED WITH THE ANTITOXIN.

BY CARL FRESE, M.D.,
OF PHILADELPHIA.

THE following case of true diphtheria was treated by the early administration of Behring's antitoxic serum, and the disease ran a remarkably rapid and favorable course.

H. S. G., twenty-three years of age, a male, had felt unwell for three days, with headache and slight pain on swallowing. He was seen by Dr. A. Hand, Jr., on January 15, 1895, at 10 A.M., who found the temperature 99.4°, pulse 85, and the face slightly flushed. The man complained of pain on swallowing. Examination of the throat revealed small patches of membrane on the pharynx behind both pillars of the fauces. The right tonsil was covered uniformly with a smooth, yellowish membrane. The breath was exceedingly offensive. The gland below the angle of the jaw on the left side was painful and enlarged; that on the right side was tender only. From bacteriologic tests Dr. A. C. Abbott reported on the 15th, at noon, that he had obtained a pure culture of Klebs-Loeffler bacilli.

On the afternoon of the 15th the temperature had risen to 102°, the pulse was 105; there was violent headache, the face was very flushed, there was great nervous depression, and thick membranes existed on both tonsils. Six-hundred normal antitoxin-units of Behring's serum were injected in the hypogastric region at 5 P.M. Just before the injection another culture on blood-serum was taken, and this, after twenty-four hours, was shown to be a pure culture of Klebs-Loeffler bacilli. No change was observed late at night except that the headache had abated a little. On the 16th, in the morning, the membranes were about the same, though the general condition was much better. The temperature was now 99°. In afternoon improvement was marked, the tonsils being devoid of membrane, and on the pharynx only a few little patches persisted. On the 17th the general and local symptoms showed still more improvement, and on the 18th the patient was apparently cured, the tonsils and pharynx being quite free.

The patient had given the impression as of a severe infection and grew rapidly worse until a few hours after the injection of the antitoxin, which seems therefore to have arrested the further development of the disease. The bacteriologic report from two independent sources (University of Pennsylvania and German Hospital Bacteriologic Laboratories) make the diagnosis of true diphtheria absolute.

A friend rooming with the patient felt unwell on the 15th and complained of soreness of the throat, which was very red, but had no membranes. In the afternoon ten drops of Behring's serum were injected. This gentleman nursed his friend night and day, and although he was run down, he developed nothing further, and his sore-throat disappeared a day after the injection. It seems very probable that this patient was immunized by the small dose administered.

No swelling or symptoms of inflammation developed in either case at the point of injection. Local tenderness persisted for two days in the second case, while in the case of developed diphtheria it disappeared within twelve hours.

GERMAN HOSPITAL.

PATHOLOGIC NOTE.

DIMINUTIVE LIVER FROM AN INFANT.[1]

BY AUGUSTUS A. ESHNER, M.D.,
ADJUNCT PROFESSOR OF CLINICAL MEDICINE IN THE PHILADELPHIA POLYCLINIC.

THE liver that I have the privilege of presenting has been placed in my hands by Dr. R. E. Müller, of this city, who has also kindly furnished me with such clinical and pathologic data as were attainable. The specimen came from a male infant delivered at term with forceps, after a labor lasting forty-eight hours, and weighing seven pounds one ounce at birth. The mother was a German, thirty-two years old, with a justo-minor pelvis, who had led a dissolute life for many years, but denied that she had ever previously been pregnant. She had been in the habit of lacing tightly, even during the pregnancy. There was no history of syphilis or tuberculosis. For the first two days of life the infant was fed on sugar-water, as the mother was unwilling to put it to breast on account of sore nipples. On the third day the child was given the breast, but it refused to nurse. It was then fed with sterilized milk sweetened with milk-sugar. Forty-eight hours after birth the face and chest of the child were observed to be icteric, and soon afterward the conjunctivæ and the extremities also. An effort was made to collect the urine for study, but without success. The stools had a greenish color on the second day. The child wasted rapidly, and died on the eighth day of life. The umbilical cord had been carefully ligated, and the ligature had not fallen off.

---

[1] Presented to the Philadelphia Pathological Society, January 10, 1895.

At the post-mortem examination it is said that no abnormality was found, save the general icteric discoloration of the tissues and the diminutive size of the liver. The ductus venosus was patulous. The dimensions and weight of the organ were not noted at the time of its removal, but after having been preserved in alcohol for some time the transverse diameter was found to be 3½ inches, the antero-posterior diameter 2¾ inches, and the vertical diameter 1⅜ inches; the weight was two-and-one-quarter ounces.

The specimen appears to me a unique one. I have been unable to find a reference to a parallel observation. In conformation, in fissuration and lobulation, and in histologic structure it presents the appearances of a normal viscus, its only peculiarity, so far as I can discern, consisting in its striking diminutiveness. Malformations of the liver are said to be, on the whole, rather uncommon. Ziegler states that the liver may be entirely absent, though rarely. Although the liver progressively increases in size from the period of its first appearance in the process of development, its relative size, as compared with the weight of the body, begins early to diminish gradually and progressively. Thus, in the first month of fetal life the weight of the liver represents one-half of the entire weight of the body; at birth the ratio is 1 : 18 or 20, and in adult life from 1 : 36 to 40. In the specimen presented this ratio is 1 : 50. I have been unable to obtain any satisfactory figures as to the dimensions of the liver at various periods of development. At birth the organ is said to extend almost to the level of the umbilicus. The average figures for the adult liver are: For the transverse diameter, 11 inches; for the antero-posterior diameter, 7 inches; and for the vertical diameter, 2.5 inches. The weight of the adult liver is from fifty to sixty ounces. In this specimen the right lobe is the larger, as it should be normally at birth and thereafter. Until the fourth month of fetal life the two lobes are of about equal size, but after this the left is the smaller. The comparatively large size of the liver in the fetus is ascribed to the large supply of blood sent through the organ from the umbilical vein.

I am at a loss for an explanation of the abnormality of size in the specimen presented. I am scarcely willing to make the tight lacing the active factor.

The Fifth District Branch of the New York State Medical Association will hold its eleventh annual meeting in Brooklyn on May 28, 1895. All Fellows desiring to read papers are requested to notify the Secretary, Dr. E. H. . O. Box 760, Brooklyn.

MEDICAL PROGRESS.

On Local and General Immunity.—As the result of an investigation based upon experimental erysipelas in animals, together with some observations on the mode of growth and the life-history of the *Streptococcus erysipelatis*, Cobbett (*Journal of Pathology and Bacteriology*, vol. iii, No. 1, p. 38) has found that cultures of the streptococcus cease to grow in beef-broth after three or four days, the majority of the cocci dying a few days later; a few remain alive and capable of producing a new growth when sown on new culture-media, for ninety days, and probably longer. The cause of the cessation of growth in beef-broth is an exhaustion of the nutrient material, and not the production of a bactericidal substance. Cultures of the *Streptococcus erysipelatis* maintain their virulence when grown on solid media, but become greatly attenuated when grown in beef-broth. The virus that has become attenuated by cultivation in beef-broth may be intensified by growing in the bodies of animals. The injection of streptococci or their products into the abdominal cavity confers immunity to a second injection, in the same situation, of more virulent cultures in quantities fatal to control-animals. Cutaneous erysipelas completely protects the parts directly affected against subsequent inoculations of the virus—in other words, it confers an absolute local immunity, while on the rest of the body it confers a general immunity, which is less constant, sometimes protecting completely, at other times modifying the course of the disease, while in some instances it is entirely absent. Intra-abdominal injections of attenuated cultures of streptococci confer a somewhat more perfect immunity upon the rest of the body. Both local and general immunity are of short duration, and do not last more than a few weeks. When streptococci are introduced into the ears of rabbits protected by recent erysipelas an inflammatory reaction quickly appears, and has already subsided before inflammation has made any considerable progress in the control. The rapidity of the onset and the intensity of this inflammatory reaction are most marked in ears locally protected, less marked in those that share in the general immunity produced by erysipelas in the opposite ear; that is to say, it is proportionate to the immunity observed in these three classes of cases. A similar difference in the inflammatory reaction of immunized and normal parts is observed when filtered cultures or dead streptococci are introduced. This power of quickly reacting is an important factor of immunity, both general and local. This same power of reacting is acquired during the course of the disease and is the cause of recovery.

End-to-End Union of a Divided Vas Deferens.—W. J. Mayo and C. H. Mayo (*Annals of Surgery*, vol. xxi, No. 1, p. 35) have reported the case of a man, twenty-two years old, who for three years had suffered from a large varicocele of the left side, and who, six weeks before coming under observation, had received a severe kick, by which the tissues of the spermatic cord were badly injured. He presented a painful enlargement of considerable size, involving the whole of the structure of the cord, separated by a space of an inch from the testicle below, which was somewhat enlarged.

A free incision revealed a mass of injured veins, with an acute angle in the vas deferens, which had been lacerated and was occluded. The cord was completely resected, including an inch-and-a-half of the vas deferens. The stumps of the cord, exclusive of the vas deferens, were ligated with catgut, and the ligatures knotted together, thus raising the testicle to a higher level. A round intestine-needle, threaded with a strand of No. 4 catgut, was pushed into the lumen of the lower end of the severed vas deferens about three-quarters of an inch, and turned out through its walls laterally, drawing the catgut through. The needle was unthreaded and rethreaded upon the opposite end of the vas deferens three-quarters of an inch, and turned out through its lateral wall. The two ends of the vas deferens were now slipped together along this internal splint, like beads on a string, until they met end to end. Knots were tied on the catgut at each point of emergence from the vas deferens to form a shoulder and prevent slipping with separation. The wound was closed without drainage, and healed promptly. The patient was dismissed in eighteen days with the testicle in its normal condition. On re-examination, a month later, the result was found to be perfect.

Hemophilia at the Onset of Menstruation.—Olivier (*Journal de Médecine de Paris*, 1894, No. 31, p. 379) has reported the case of a girl, thirteen years old, who had just menstruated for the first time, the discharge at first being slight, but subsequently becoming so profuse as to threaten life. All other measures failing, the vagina was tamponed and the flow was moderated. Upon the removal of the tampon, at the end of twenty-four hours, the hemorrhage was resumed with its previous freedom. Vaginal injections of hot water were employed and followed by the introduction of a tampon, but without success.

Upon consultation, the conclusion was now reached that the girl was a hemophilic. It was learned that when a child, she had fallen, injuring the head, and a large ecchymosis had formed beneath the scalp. The removal of teeth at different times had also always been followed by free bleeding.

The following plan of treatment was outlined: 1st, vaginal injections, at a temperature of 122°, every two hours; 2d, if the hemorrhage persisted, galvano-caustic intra-uterine application of 50 milliampères, followed by a tampon; 3d, treatment directed toward the general condition, especially alcohol in some form; 4th, the hourly administration of hydrastinin. In this way it was hoped to control the immediate bleeding. The question also arose as to its repetition in the future. The removal of the ovaries in the hope of obviating such repetition was contra-indicated by the danger of fatal hemorrhage from the operation.

The Enlargement of Subcutaneous Lymphatic Glands in the Tertiary Period of Syphilis.—Montgomery (*Festschrift zur 25. Jaehrigen Jubilæum des Vereins Deutscher Aerzte zu San Francisco*, 1894) calls attention to the liability of mistaking the enlargement of the subcutaneous lymphatic glands observed in the tertiary period of syphilis for leukemia or lymphadenoma or tuberculosis. He reports several illustrative cases in which subsidence of the enlargement followed discriminating and persistent use of anti-syphilitic remedies. In some cases of secondary syphilis in scrofulous individuals the lymphatic glands become enormously enlarged and may persist after the antecedent lesions have disappeared.

Strontium Salicylate.—Wood (*University Medical Magazine*, vol. vii, No. 4, p. 219) has employed strontium salicylate in a large number of cases of various kinds, in doses of from fifteen to twenty grains a day, and has found that in doses of from five to ten grains, given after meals, the salt very commonly improves digestion, and in the dose of five grains an hour after meals, in flatulent dyspepsia and various conditions of tendency to fermentative changes in the alimentary canal, it is a useful antiseptic. It does not produce cinchonism as readily as do the other salicylates, though it is entirely capable of causing a pronounced degree of cinchonism. It was found to be valuable in the treatment of muscular or subacute rheumatism, as well as of chronic gouty conditions with a tendency to digestive disturbances, exerting the action of the salicylate upon the diathesis and improving digestion. The drug may be given in solution, but is best administered in capsules of five grains each, of which two or more may be taken at once.

THERAPEUTIC NOTES.

The Treatment of Diphtheria with the Antitoxin.—Ganghofner (*Prager medicin. Wochenschrift*, 1895, Nos. 1, 2, 3) has reported 110 cases of diphtheria treated in the Kaiser Franz Josef Children's Hospital at Prague with the antitoxin, with 14 deaths, a mortality of 12.7 per cent. Of the whole number, 44 required operative relief of laryngeal stenosis, with 6 deaths (13.6 per cent.). Among 144 cases treated in the intervals of antitoxin-treatment and immediately preceding, there occurred 62 deaths (43 per cent.); 67 required intubation, and of these 41 died (61 per cent.). The mortality in previous years with other methods of treatment had ranged from 43.6 to 63.6 per cent.

Morrill (*Boston Medical and Surgical Journal*, vol. ccxxxii, No. 4, p. 80) has reported the occurrence of three outbreaks of diphtheria in the Boston Children's Hospital and the threatened development of a fourth despite thorough cleansing and disinfection. At this stage systematic employment of the antitoxin was instituted, both in cases of diphtheria and in those of other kind, with the result that in a short time the hospital was free from diphtheria.

In the Treatment of Carbuncle Tischer (*Festschr. zur 25. Jaehr. Jubil. des Ver. Deutscher Aerzte zu San Francisco*, 1894) recommends parallel incisions about an inch apart extending to the subcutaneous connective tissue and on either side into healthy structure, and crossed by another series of parallel incisions at right angles. Subsequently the wound is irrigated several times daily with a solution of mercuric chlorid, dusted with a powder of mercuric chlorid and white sugar, 1 : 1000, and covered with gauze.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 Walnut Street,
Philadelphia.

Subscription Price, including postage in U. S. and Canada.

Philadelphia.

SATURDAY, FEBRUARY 2, 1895.

SUGGESTIONS TO OUR CONTRIBUTORS.

THERE are two reasons why we wish to-day to offer our contributors a few hints in reference to the matter and manner of contributions to medical literature. The first reason is a selfish one, and relates to editorial labor. Many journals keep a standing column of "Notices to Correspondents" concerning the preparation and forwarding of articles; but, despite all reiteration of such advice, it is habitually disregarded, and the same mistakes are repeated in almost every second manuscript sent for publication.

In the hope of calling more marked attention to the matter, we therefore appeal thus directly for the not inconsiderable motive of saving future editorial labor.

But the motives are not wholly selfish, and a second one relates to other editors and to the contributors themselves. We have no doubt that many a worthy contribution to medical literature has failed to reach its proper medium of communication, or has failed to attract the attention it really merited, because of failure in the method of presentation. And very frequently such failure depends fundamentally upon something that the writer considered beneath notice. Editors are very fallible folk, as well as very busy, and the chances of the acceptance of a proffered manuscript containing, perhaps, most excellent matter, are less probable if written so illegibly as to be read only with much weariness to brain and eye; if in the very title *Iliac* is spelled *Illiac;* if the paper is rolled so that it requires four hands to hold it open for reading, etc. We well understand that one noteworthy editorial duty is to look through and past the defective presentation to the real value of the thing presented, and when editors shall have sloughed all imperfection and finiteness this will be done. In the meantime we believe that an article will run the better chance of acceptation by the best journals, it will reach the best class of physicians, and it will be read by a greater number of that class, just in proportion as the writer fastens the following suggestions well in mind, and in writing carries them out.

As in all literature, so in the medical variety, all good writing depends upon good thinking and in having something of value to set forth. Teachers of rhetoric and those untrained in literary labor are very prone to talk about style and the acquirement of style. But this is all folderol. "The style is the man." There is or there should be no such a thing as style in medical writing. The thing to do above all things is to get rid of style. The best style is no style. To think the whole matter out clearly, in advance of putting pen to paper, and then to state it in the simplest, shortest, most uncolored way, is what is most desirable. Every article written with the secret desire to advertise the writer betrays to the trained eye the unmistakable evidences of that secret desire, and by that much lessens the value of the writing. How much more evident must it be if the desire to advertise is the sole motive, when there is little or nothing of scientific value to communicate, and when general haziness of thought is manifest in every line. To have something of use to medicine and to one's fellow-workers about which to write, to think it out thoroughly in advance, and to state succinctly and clearly what this something is—these are the chief secrets of good medical writing.

Brevity is said to be the soul of wit; it is certainly the body of good judgment. There is a story of a great charity-sermon which was at once the most effective and the briefest on record. It consisted of a doubly emphatic announcement of the text: "He who giveth to the poor, lendeth to the Lord," followed only by the words, "Now, brethren, if you are satisfied with the security, down with the cash!" To say what one has to say perspicuously, without introduction or peroration, and without redundant words, is the aim of a good writer. The contributor is likely to think the editor harsh and autocratic who begs for condensation, who excises useless words, "fine sentences," exordiums, excuses, and all the other things that prevent, not aid, the author in the communication of his thought. But these things are so many obstacles hindering the many from reading. Every word that is useless or that directs the attention to the writing, or to the writer, rather than to the thought and the thing written, is just so much friction-material placed between the two minds. The more round-about the way the longer is it; the more the attention is called to the roadway the less perfect it is. The object of good scientific writing is the transference of thought; the more the reader's attention is compelled to busy itself with the medium of transfer, the less speedily and easily is the transfer itself made.

One of the first laws of the literary decalogue is that a grammatical sentence must have at least a subject and a predicate, and yet we have spent as many as several hours over a single manuscript making sentences conform to this primal commandment. One wonders whence has come the fashion in medicine of reporting case-histories in jerky, meaningless spirts and fragments of sentences, either subjectless or predicateless, usually also articleless and always ridiculous. For example, one receives something like this:

> Case I. A. B. Æt 23 Irish Seen 9th Temp 102½ Pulse 90 Resp 30 Albuminuria mind good great weakening No app Sick 10 days Tubbed Prescribed as usual. 10th, Temp. 101⅖—etc.

Now, when originally written or transcribed from the note-book, why should this not have been translated into the English language? It were quite as easy to write, and certainly more easy to read it, if written somewhat as follows:

> Case I. On January 9, 1895, I was called to see A. B., twenty-three years of age, of Irish parentage, who had been ill for ten days. His temperature was 102.5°, the pulse-rate 90, the respirations 30 to the minute. Albumin was present in the urine. The man's mental condition was good, but there were great physical weakness and loss of appetite. He was given a cold bath, and the usual medicines were ordered. On January 10th, the morning temperature was 101.4°, etc.

We could fill an entire issue of The News with suggestions as to matters grammatical, but we fear it would be useless, and it might be considered in ill-taste. The world will doubtless end before even the best writers will learn the proper and discriminating uses of *that*, *which*, and *who*, the right and sufficient use of compound words, the function of hyphens, as well as of other punctuation-marks, and a hundred like things. We wish, for instance, very much that people would not use *where* when it does not express their thought, and when *in which* or *when* does express it. There are dozens of little manuals that will give one who seeks stores of useful information in all these things, and the time spent in their study is never lost. Terseness and perspicuity of thought are largely products of the diligent study of the right use of language. If one writer more than another may be commended, we would, as a model, direct attention to one whose vigor and originality of thought were universally admired, one whose pen, alas! is now forever at rest. Few knew the scrutinizing care bestowed upon his sentences by that master of medical English, Dr. William Goodell. The limpidity and force of his words and sentences seemed so spontaneous and natural that one can hardly believe the pains he took with almost every one. He knew well enough that language is the maker as well as the servant of thought. The effort to be scholarly, to use fine language, to be "highfalutin," is the bane of many writers. To write as one would speak, simply, in short sentences, in clear, clean, old-fashioned Anglo-Saxon is the "one thing needful."

Lastly, why not be modern, scientific, crisp, American? As to chemic nomenclature and spelling we would refer our readers to the suggestions made in The News of June 17, 1893, p. 660; of December 24, 1892, p. 722; and of August 22, 1891, p. 221. Progress in philology is as inevitable as progress in therapeutics, and the fetichistic clinging to antiquated usage in one is as nonsensical as it is in the other.

Contributors sometimes feel hurt because their manuscripts are not accepted, but there are a large number of reasons besides lack of merit that often compels the rejection. If The Medical News were many times its present size it would be impossible to find space for the great mass of material offered.

Much must, therefore, necessarily be returned. But apart from this, a paper cannot, perhaps, be accepted because, for example, we have already accepted or have published as many articles on a particular subject as, for variety's sake, is advisable; because it is an article of interest to the specialist alone (and The News is a journal addressed to the general physician) or to a limited circle of readers; because while good of its kind it is too much a restatement of known or accepted truth without positive addition to medical science, etc. Then some manuscripts are at once seen to require for proper presentation such a frightful amount of "editing," so many elisons, inversions, additions, and corrections that the poor editor would evidently get no time to sleep should he do his duty to the essay and its author, with the added probability that the author would consider that his writing had been utterly spoiled, and thereafter would he be forever angry, instead of duly grateful, as he should of course be.

If every article were published simultaneously in each of the 234 American medical journals, how useless would become all of the journals except one, and how absurd would be that much manifolded article! There is hardly a week that either, through inadvertence or a most remarkable peculiarity of mind, copies of one and the same article are not received by many journals, as if for the exclusive use of each. Sometimes the titles or a few lines of introduction are changed so as to make it appear at first glance as a different article. One journal publishes it first, the others have the trouble of editing and the expense of type-setting and of proof-reading, after which it has, of course, to be "killed," because it has appeared elsewhere first. One hesitates to characterize such a proceeding in deserving and plain English; it is certainly exasperating in the extreme. It may be due to gross stupidity, or to flagrant trickiness. In the case of The Medical News, which pays for contributions, it is doubly dishonest; but in the case of every journal of character it is culpable deceit, to say the least. The editor proceeds upon the thousand-times repeated understanding that articles contributed are for the exclusive use of his journal. It is this singleness of publication that gives the article value both for the journal and, if he but knew it, for the author also. What value would an artist's pictures have if he painted a dozen exact copies of each original? What would be thought of that artist's honesty if he did so?

The Medical News gives for articles either 250 reprints or a cash credit. It does not give both, and it is necessary for contributors to choose which they prefer. When no preference is expressed, it is understood that the credit is desired instead of reprints. It is remarkable how frequently writers request or suppose that their article will appear "in the next issue," forgetting how impossible that would be, and how unjust it would be to others whose papers have been previously accepted. As a little detail of business, it is not always convenient for remittances to be made the exact instant following publication. About once in three months would seem to be reasonably frequent to make up the accounts.

There is the illegible hand-written manuscript, and there is the type-written manuscript, with the medical and orthographic ignorance of the type-writer glaring in every other word. The long-suffering editor hardly knows which is the worse. Type-writers, of course, cannot be supposed to acquire as a part of their stenographic education a knowledge of medical nomenclature and science; neither has the machine been invented that will mechanically spell our remarkable medical terms with infallible correctness. If the type-writer is used, the physician should revise her, his, or its work with his medical understanding; and if the manuscript be really manu-script, chirography and punctuation should be deemed matters worth careful consideration.

Writers should use good paper, say 8 x 10 inches in size; there should be a full inch of blank space at the left-hand side of the page, and the lines should not be too closely written. Very few writers "paragraph" correctly, and editors, therefore, much prefer that this be left as a part of the editorial work. Write "solid," putting all foot-notes immediately in the next line below that containing the asterisk, and proceeding with the text when the foot-note is completed. Draw a vertical line opposite the foot-note in the blank space at the left. If one has a drop of the milk of human kindness in his veins, he will not write on both sides of a sheet of paper, and he will not roll his manuscript. Mail if possible without folding; but if necessary to do so, fold it once, or not more than twice. Having had a single experience, both editors and publishers are thereafter afraid of a man who rewrites his article on the galley-slips.

EDITORIAL COMMENTS.

Priority Claims.—Some time ago we commented upon the mental and moral condition of the "priority-killer"—by which term we meant one that seeks to invalidate the just right of another to the honor of having discovered a new truth or of having devised a new procedure in medicine. There is, of course, a lack of dignity in asserting too often and too loudly one's own claim as a discoverer. But there is something positively disgusting in trying to rob another of his proper meed of honor in this respect, and when such covert attempts are in progress one is justified in making his own relation to a discovery clear and evident. The ignominiousness of the one who seeks to minimize, dispute, or steal the priority-rights of another consists in the method in which it is done, in the fact that the secondary claim cannot rob the discoverer of *all* his due, and in the fact that the secondary claim lacks the absolutely essential proof of the printed account preceding in time that of the primary claim. We are all wise after the event. After one has published a discovery any other who says, *I did this, or knew this years ago*, is guilty of a lack of generosity and of a culpable desire to steal another's merit. Even if discoverer No. 2 had, in truth, independently discovered or devised the thing prior to the publication of No. 1, the fitting thing for him to do would be to "keep mighty still," unless he can prove it by better means than *ipse dixit* and by "patients." Even stupid minds quickly recognize the devious ways of professional jealousy. One smiles when a writer solemnly describes "an old method" he has used in his private office "for twenty years," or "for many years," and then goes on to say, "This is essentially the same as the excellent method recently promulgated by so-and-so," etc.

We started out to describe a recent illustration of the procedure in question. As all surgeons now know and admit, to Dr. J. William White, of Philadelphia, belongs the honor of priority in devising and scientifically establishing the value of orchectomy as a radical means of cure in enlargement of the prostate gland. If the principle of eponymic nomenclature were ever justifiable, it is in this case, and we doubt not that the operation in question will be known as *White's operation* so long as personal nomenclature obtains. But an English surgeon has had the bad taste to speak of the operation as follows:

> "As frequently happens in such cases, the same idea appears to have occurred more or less definitely to many people almost at the same time. In November, 1892, I discussed the advisability of the operation with a patient, who, though he admitted the force of the arguments in favor of it, not unnaturally declined it on the ground that it must be of the nature of an experiment. In 1893, in an admirable paper read before the American Surgical Association, Professor White, of Philadelphia, summed up all that was known in favor of it, admitting that he had, as yet, formed no convictions upon the subject," etc. [Moullin, *Enlargement of the Prostate.*]

Now several things are to be noted in this excerpt: 1. There is no disputing the fact that the same idea *may* occur to several people at the same time; but the point is, did it, in this instance, occur to several? Proof is necessary. 2. Why the expression, "to *many* people?" It is only a question here of *two* people. 3. Why not produce even the *patient's* affidavit? 4. The word *admirable*, as applied to Dr. White's paper, is fine. To filch priority and detract attention by such flattering adjectives as *excellent*, *admirable*, etc., is simply detestable.

The same characteristics appear in a letter to the *British Medical Journal* of January 12, 1895, in which Mr. Moullin says:

> "Those who impute motives to others are seldom quite correct, and Professor White is no exception to the rule. It is, of course, annoying to Professor White to find that an idea which he thought peculiarly his own had occurred independently to others (who were acquainted with John Hunter's work), and had already been successfully put into practice by Ramm, but it is none the less true. As I have already answered Professor White fully elsewhere, I must decline to take any further notice of his remarks about me."

The most prominent compatriots of Dr. White's critic, such as Lister, Treves, Buckston Browne, MacMunn, and others, as well as a very large number of Dr. White's own countrymen, do not admit that Mr. Moullin has by any means either established his own claim or in the least invalidated that of Dr. White. All he has done is, disastrously for himself, to illustrate an unworthy and too common characteristic and practice. The best thing now for him to do, as he has evidently recognized, is to retire too late into the pompous dignity and reserve from which he should never have emerged.

A Climatologic Investigation by the United States Government.—The influence of climate both in the production and in the treatment of disease has long been recognized, and we are glad to learn that an earnest and systematic effort is about to be made under the auspices of the United States Government, through the Weather Bureau of the Department of Agriculture, to gather such data as must ultimately prove of the greatest value to sanitarians in the selection of places of residence with a view to the prevention and cure of disease. The work has been placed in the hands of Mr. Mark W. Harrington, the efficient Chief of the Weather Bureau, who has already in many ways manifested an active interest in the subject of sanitary climatology.

In the official announcement it is pointed out that the study of the climates of the country in connection with the indigenous diseases should be of material service to every community, in showing to what degree local climatic peculiarities may favor or combat the development of different diseases, and by suggesting, in many instances, supplementary sanitary precautions; also by indicating to what parts of the country invalids and health-seekers may be sent to find climatic surroundings best adapted to the alleviation or cure of their particular cases.

The hearty coöperation of the various boards of health, public sanitary authorities, sanitary associations and societies, and of physicians who may feel an interest in the work, is asked, to the end of achieving and perfecting the aims of this investigation.

It is proposed to send, free of cost, the publications of the Bureau bearing upon climatology and its relation to health and disease to all those who assist in the work.

Coöperation will consist in sending to the office of the Chief of the Weather Bureau of the United States Department of Agriculture, at Washington, D. C., reports of vital statistics from the various localities. That these reports may be of value, they should be accurate and complete, and be rendered promptly and regularly. Accordingly, blank forms of reports have been prepared so as to occasion as little trouble and labor as possible on the part of the reporter, and will be furnished by the Bureau on application. It is pointed out that at the very beginning of the investigation it is not possible to outline precisely the channels through which the results obtained will be made public, but it is hoped to publish soon a periodical devoted to climatology and its relations to health and disease. The publication will probably resemble in size and general appearance the present *Monthly Weather Review*, the subject-matter being, of course, different.

English at the United States Military Academy.—From the interesting Report of the Board of Visitors of the United States Military Academy we learn that out of 1375 hours of study in three years, devoted to modern languages, 294 are given to English, and the entire remainder to Spanish and French. German is entirely omitted. The committee was "rather painfully impressed in the examinations with the halting English of a number of the cadets." The recommendation of the committee is that some of the time given to other studies be given to English—a plan that would seem most desirable. But better yet is their suggestion that the standard of entrance-requirements be elevated. We surmise that the difficulty lies in the use of the Academy by Congressmen to get schooling for the boys of their friends at home. Concerning faulty education in the mother-tongue, this grave fault lies at the door of very much of our so-called education. There is a sad straining after the showy and the *omne ignotum* rather than an attempt to render effective the use of our own language. We have known pupils to study rhetoric, trigonometry, French, Latin, etc. etc., when they could not spell ten common English words correctly. Concerning the elevation of the entrance-standards the committee says:

> "This would only require probably six months more of study before entering the Academy, and would provide very much needed time for English, history, ethics, hygiene, and possibly for German.
>
> "It is urged that this will cut off some poor boys who otherwise might enter, and even graduate. Even were this true, it would be better to cut off a few ill-trained poor boys entering as officers than by a less thorough training of the whole corps of cadets to expose the thousands of poor men in the ranks to the evils of poorly equipped officers. But West Point exists neither for the poor boy nor the rich boy, but to give the country the very best and most efficient officers to command its Army, upon which often depends security of life and property, public and private, in cases of domestic disturbances, and upon which must always absolutely depend victory in time of foreign war. No officer can be too well trained for such a command. It is very easy to provide officers too poorly equipped, and so invite defeat.
>
> "The increase suggested in the conditions for admission is very moderate. The present requirements were formulated nearly forty years ago, when our public schools were poor and scattered, and the instruction given in them was very limited. This is not true now. The enormous strides in general preliminary education should cause our war college also to make equal advances. The public schools are ready to furnish better students just so soon as West Point will take them."

The Transmission of Typhoid Fever through the Intermediation of Oysters.—The conclusion recently suggested (see THE NEWS, December 8, 1894, p. 641) that typhoid fever may be transmitted through oysters, as based upon the occurrence of an epidemic among the students in a New England University, receives confirmation from the report of analogous occurrence in England. SIR WILLIAM BROADBENT (*British Medical Journal*, January 12, 1895, p. 61) reports quite a collection of cases in which typhoid fever developed in individuals under circumstances in which the infection had to be ascribed to the ingestion of raw oysters. This relation has been suspected in the past, but the evidence was never as conclusive as that furnished by the more recent experiences. The simplest means of prophylaxis, other than abstaining absolutely from the use of oysters, is to have them cooked; but it seems that steps should be taken to prevent contamination of the waters in which oysters are either grown or placed temporarily for their improvement.

EADE (*British Medical Journal*, No. 1777, p. 121) has further pointed out that not alone oysters, but also other forms of shell-fish, as, for instance, mussels, are capable of transmitting typhoid fever. He cites an epidemic of typhoid fever in a community of which the poorer classes were especially affected, and among whom mussels were largely used as an article of food. These fish, being stored in the beds of streams until disposed of by sale, are peculiarly liable to be contaminated and to constitute the means of transmitting the infection.

"*The Missing Link*" has been discovered, and all Darwinians may now in concert exclaim, *We told you so!* DR. EUGENE DUBOIS, of the Dutch East India Army, has found our common revered progenitor in the late Pliocene or post-Pliocene deposits of the island of Java, and he gives this long-sought-for ape-form the fitting name of *Pithecanthropus erectus*, pronouncing it to be the intermediate form between man and the true anthropoid apes. The cranial arch is said to be surprisingly pronounced, falling almost half-way between that of the chimpanzee and that of man, while the cranial capacity approaches to the physiologic minimum of man, and is double that of the gorilla. The femur is the analogue in form and dimensions of that of man, and must have supported an erect body. We are delighted that the matter is settled, so that we may go on with the work of human perfection, knowing at last exactly where our family-tree begins and where we now stand.

Mr. Ernest Hart in India.—That indefatigable traveller and preacher of hygienic morality, Mr. Ernest Hart, has carried the war into India, and has been seeking to hammer into Mahomedan ears and understandings the great lessons of sanitation and preventive medicine upon which not only the health of the Orient but that of the Occident depends. Under the auspices of the Mahomedan Literary Society of Calcutta, and before a large gathering of European and Mahomedan gentlemen, Mr. Hart ingeniously and powerfully pleaded for the extinction of Meccan cholera by the means well known to all civilization but which are so profoundly needed in the East. For this tirelessness in a noble work the whole world is deeply indebted to Mr. Hart, and we hope his eloquence may not be wasted upon our Mahomedan brethren.

SELECTION.

MEDICAL PROGRESS IN INDIA.

My period of service, now close on thirty years, has been marked by enormous progress in all directions. Medical colleges, in which a complete education is given in English, have been opened at Lahore, Allahabad, Tanjot, Nellor, and affiliated to the universities. At Haidarabad the classes have been taught in English since 1882. Additional vernacular medical schools for the education of civil hospital assistants and civil medical practitioners are now working at Sealdah, Patna, Dacca, and Katak.

The medical education of women has also been recently introduced, and girls are now trained for the purposes of the Dufferin Fund at most of the medical schools. The number of hospitals and dispensaries open last year was 2025, in which were treated 16,973,468 patients, increases of 76 and 176 per cent. over 1877. There were 4476 operations for stone, 20,279 for cataract. Vaccination has been enormously extended and put on a much more systematic footing; 7,502,024 operations were done, an increase of 62 per cent. These figures indicate great activity and afford ground for congratulation, yet, compared with the wants of the country, indicate that they still touch but the fringe of the population. In Bengal, for instance, only one-fifteenth of the people are within five miles of a dispensary, and a considerable percentage of the children born escape vaccination, so that bad epidemics of smallpox are still possible. Of recent years an entirely new development has taken place in the organization of special hospitals for women officered by medical women, under the fostering care of the noble Lady Dufferin, whose name, like Milton's, should resound for ages among the zenanas of India. Still in its infancy, it is doing enormous good to a class whose needs are of the sorest, and it is, I believe, destined to flourish and increase until every important town in India has its Dufferin Hospital side by side with its hospital for males.

Sanitary progress, however, is the chief feature of the last thirty years, and more especially of the last decade. I have told you how the death-rate of British soldiers up to 1857 averaged 69 per mille, and that the Sanitary Commission ventured to hope it might be reduced to 20. This estimate was too modest, for since 1882 it has never exceeded 15, except in 1889, when it was 16.6, less than a quarter of the previous rate. The reduction has been effected by hygienic reforms of all kinds, but especially by the gradual improvement of the water-supply in cantonments, first by cleaning and protecting wells and tanks and setting them aside for drinking purposes only, a plan which has been followed for many years; and of recent years by scientifically devised water-works provided with all the latest improvements. —*From the address of the President, Surgeon-Colonel Harvey, at the opening of the Indian Medical Congress, December, 1894.*

SPECIAL ARTICLE.

MILK-INSPECTION AND MILK-STANDARDS.[1]

By HENRY LEFFMANN, M.D.,
OF PHILADELPHIA;
MICROSCOPIST AND FOOD-INSPECTOR, PENNSYLVANIA STATE BOARD OF AGRICULTURE.

[Reprinted from advance sheets of the forthcoming annual report of the Board.]

No topic in sanitary science has received greater and more careful attention in the past twenty years than the analysis of water and milk, and few topics have exhibited greater transformations as to the principles on which judgments as to sanitary value may be based. The extension of bacteriology has enabled us to identify the causes of disease and to demonstrate in many cases the methods of propagation.

In water-analysis we can still rely with much confidence on the merely analytic results, though we recognize that the figures for chlorin, ammonia, and so on, are merely indexes of pollution and not injurious in themselves. In milk-analysis, we have first been obliged to correct our analytic methods, and, lately, to revise materially our views as to the manner in which milk affects the public health.

In the judgment of the results of a water-analysis, chemists have never been misled into attaching undue importance to the proportion of dissolved matters; but in judging of the results of milk-analysis this error has long been made, and is still being made by sanitary officers. Thus, in the early days of the agitation of the question of milk-inspection in Pennsylvania, reference was not infrequently made to the high rate of infant-mortality, and this was ascribed to the reduction of the strength of the milk-food by dilution and skimming.

At the present day we are in possession of a much wider and more exact knowledge as to the manner of the distribution of disease by milk. We now know that serious dangers arise from the contamination of the milk by microbes, and that such dangers fall practically into two classes.

The first class is that due to contamination of milk by specific micro-organisms from disease, either among the milk-yielding animals or among the persons about the farm. I do not think that it will be necessary to discuss these questions in much detail, for all are pretty familiar with the subject. Possibly, some may not fully appreciate the extent to which specific disease in dairy cows exists, and to which it infects human beings; but I frankly say that I am a convert to the view that the production of cows' milk for human food, under the present methods of collection and use, is one of the most dangerous of human industries. As an illustration of the extent to which tuberculosis may exist in herds, I take the following articles from the *Medical Record* of January 6, 1894.

---

[1] At the annual (1894) meeting of the Board one session was devoted to the discussion of questions relating to "Milk-Standards and Milk-Inspection." These subjects were selected because at the preceding session of the Legislature the Senate Committee on Agriculture had requested the Secretary of the Board thus to introduce the question at one of the meetings of the Board, and obtain the opinions, *pro* and *con*, of those interested.

All parties interested were invited by advertisement and programs, and a number of persons known to hold diverse views were invited, to be present and explain their positions.

"Probably few physicians are aware of the enormous practical value in the animal industry of tuberculin, that is to say, if the position taken by the New York and other State Boards of Health regarding it is correct. A gentleman who has a valuable herd of thoroughbred cows writes us that twice within the last six months his herd has been examined by competent veterinarians and pronounced healthy. A third examination, however, with the aid of tuberculin, caused a condemnation of over one-half of the herd. He adds:

"'The New York State Board of Health is killing by the hundreds animals condemned by diagnosis with tuberculin, and the State is paying full value for them. The veterinarian says that the autopsy shows the diagnosis to be correct in every case.' He says, also, that it is impossible for the best veterinarian to discover tuberculosis by physical examination except in extreme cases. 'My herd is apparently in splendid condition. Breeders do not know of its existence in their herds. They let a cow remain in the herd until she is unquestionably tuberculous, and then remove her, but she has then already infected the herd. A temperature of 103° F. condemns the cow.' In a herd of Jerseys, at Troy, of 80 head, he has killed 33, and will kill 20 more of them this week. Autopsies are held in the presence of physicians and veterinarians. There have been 15,000 tests with tuberculin in England. New York evidently believes in this kind of diagnosis, and will probably have to pay $500,000 to eradicate tuberculosis. The veterinarian says the State is full of it, in herds of thoroughbreds and common cows.

"We understand from other sources that the State Board of Health fully believes in the certainty of the tuberculin diagnosis. Through its means it has been discovered that some of the best-bred herds, supplying high-priced milk, cream, and butter are infected."

It is apparent from this article, which is merely one of many similar statements, that we have not fully realized the relations of milk to the prevalence of the disease which is known to be the cause of one-seventh of the total deaths in civilized countries, and is the unsuspected cause of many more.

It is, however, not only disease in the cow which may be conveyed. The conditions of farm-life are such that milk often conveys virulent, infectious diseases from the dairyman's family to his customers. Here, again, the literature is so abundant, and the facts are so generally known, that I need not stop to detail them. Those who are interested in this phase of the question will find some valuable and recent data in the report of the State Board of Health of Massachusetts. Several epidemics of typhoid fever were traced to milk supplied from a farm on which a case of this disease existed.

We find, however, that even when milk is taken from cattle entirely healthy, and on farms in which no specific disease exists, it may become a most dangerous article of food. This is due to the decompositions which are induced in it by bacteria. Milk is a close approach to a perfect food. It is not an absolutely perfect food for human beings, because it is deficient in iron; but it serves admirably as a medium for the growth of bacteria, many species of which produce remarkable changes in the casein, by which highly poisonous compounds are set free. Now, under the ordinary methods of milking, infection with multitudes of the common bacteria of the air, water, and even soil is certain to occur. That milk usually contains these is proved by the deposits obtained in centrifugal swimming, which show, under microscopic examination, many repulsive materials. When milk as ordinarily furnished is kept at summer temperature, the bacteria increase with great rapidity, and it is now recognized that a proportion of the infant-mortality in the warmer season is caused by this condition. In fact, the information at present in our possession shows that, unless collected under extreme precaution, raw milk, at least cow's milk, is not a suitable food for human beings. Hence the general practice of sterilization, which has resulted so favorably in the feeding of infants. Statistics have been recently published which show that death from tuberculosis occurs in large proportion in infants, the action being due to the entrance of the tubercle-bacillus into the lacteals, thus preventing the absorption of the food and causing death by starvation.

I have endeavored so far to indicate briefly, but I hope distinctly, the idea that sanitary control of milk-supply may have little to do with the mere question of the chemic composition of milk. It is of very little moment to the consumer, except on a question of cost, whether milk contains 12, 13, or 14 per cent. of solids. The claim that milk watered or skimmed is unwholesome rests on no positive information, and within certain limits of variation, the regulation of the composition of milk is no more a matter of sanitary duty than the regulation of the proportion of fat and lean in the meat sold in our markets, or the proportion of alcohol and extract in beer and ale. Nevertheless, economic considerations will doubtless lead to the establishment of some standard for milk, and it will be sufficient to fix the minimum, not the average. The time is passed when we can claim 9.50 solids not fat for a standard, and even 9.00 per cent. is unjust. In my opinion, there should not be fixed in any legal enactment a higher figure than 8.50 per cent. of solids not fat, and 3.00 per cent. fat for whole milk. Skimmed milk should be permitted to be sold as such, and should not be required to contain any fat; that is, any one purchasing skimmed milk should assume that all the fat may have been removed. I have never been able to understand the logical process in the minds of those who desired to prohibit the sale of skimmed milk. However, when we remember that the same parties who last winter were trying to prevent the sale of skimmed milk proposed also to prohibit the sale of condensed milk containing less than twenty-five per cent. of fat, which would exclude all the standard brands in the market, we can appreciate the impracticable views that may be advanced.

It has been the custom of some persons to designate the skimmed milk from centrifugals as "separator slop," but I am unable to see that such an article is any more of the nature of a refuse than buttermilk, whey, or cheese.

The standard of the Society of Public Analysts of England, an organization which represents, I think, the highest judgment and experience on the question, is 8.50 solids not fat and 3.00 of fat. Concerning this standard, Dr. Vieth, a dairy-chemist of large experience, recently expressed himself as follows:

"My object is by no means to raise the cry that the standard adopted by the society is too high; on the contrary, I think it is very judiciously fixed, but in upholding the standard of purity it should not be forgotten that the cows have never been asked for, nor given their assent to it, and that they will at times produce milk below standard. A bad season for hay-making is, in my experience, almost invariably followed by a particularly low depression in the quality of milk, toward the end of winter. Should the winter be of unusual severity and length, the depression will be still more marked. Long spells of cold and wet, as well as of heat and drought, during the time when cows are kept on pasture, also unfavorably influence the quality, and, I may add, quantity of milk."

Much discussion has been given to the effects of special forms of food and their relation to the wholesomeness of milk. Legislation promoted by health-boards often involves prohibition of the use of brewers' grains or distilling refuse. In regard to these matters I desire to transcribe two personal letters received from Dr. Vieth, whom I have just quoted:

"The reason that I have not acknowledged and answered your favor of August 21st ere this, is, that I desired to give you as much information as possible on the subject of the effect of brewers' grains and similar refuse on the wholesomeness of milk.

"I suppose it is about the same in your country as it is in ours, viz.: that people are not slow in passing an opinion on the matter in question either one way or the other; but when one sets to work to follow the matter up, one finds these opinions not substantiated by facts. I was, when I received your letter, not aware of any publication on the matter in question, and have since taken much trouble to find one or collect information worthy to be transmitted to you. I am sorry to say that I have failed in my endeavors almost entirely. Hunting through the literature, I have found brewers' grains barely mentioned in connection with the question of the wholesomeness of milk—and have got the impression that no one thinks of expecting any bad effect from the use of that food. Here the question turns almost entirely about the admissibility of distillery-wash as food for milk cows. This food has a good many adversaries, but, it seems, even more defenders. It is generally admitted that, when fed in moderate quantities and in a fresh state, and other food given besides, it will do no harm. When given in large quantities—say from fifteen to twenty gallons per day—it certainly produces a very poor milk, which is said to have a bad effect on infants. This is most likely true, but I have failed to find it proved by experiments or exact observations. The best observations on the subject I have come across are made by Prof. König, and are contained in a paper which has been published in *Repertorium für Analytische Chemie*, 1881. They are also based on theoretic speculation, and not on actual experiments. Before leaving the subject I should like to mention that there is most likely a considerable difference between brewers' grains from ale and from lager beer breweries.

"When your card of the 21st ult. arrived I had just come into possession of some more evidence with regard to feeding milch-cows with distillery-wash; that is, the refuse from the manufacture of potato-spirit. Professors König, of Munster, and Maercker, of Halle, are two eminent authorities on the subject of cattle-feeding. The former is of opinion that there is no objection to giving to cows from forty to fifty liters of fresh distillery-wash per diem, provided other suitable food is given in addition. He would rather not have the distillery-wash used in a sour condition, and objects to feeding children with milk from cows which have received it. (In the prohibition of the use of distillery-wash he would see a serious injury; but it should be demanded by law that milk thus produced should all be sold in the sterilized condition.) All the objections would be overcome by the use of distillery-wash in the dried state.

"Prof. Maercker writes that the supposition that the milk from distillery-wash fed cows is injurious to health is in no way supported. The distillery-wash is completely sterilized in its manufacture, which is not the case with any other food. If milk from distillery-wash fed cows has caused illness, the fault is that proper care had not been taken to keep the cowsheds, and more particularly the mangers, clean. Under such conditions, any food might produce similar ill-effects.

"Ohlsen and Uffelmann, of Rostock, have made an investigation into the matter and published the results in the *Jahrbuch für Kinderheilkunde*, 34, vol. 1. The results are, in short, as follows:

"The milk from cows fed with distillery-wash is of neutral, sometimes alkaline reaction. Acidity did not set in before the lapse of forty-eight hours. Provided suitable food be given in addition, the milk does not appear unsuitable for feeding infants. There is no proof that the milk produces indigestion or rachitis with infants. Microscopic and bacteriologic examination did not prove any difference from other milk.

"The work of Ohlsen and Uffelmann is the first evidence on the subject, founded on exact observation, which has come to my knowledge, and as I thought it might be useful to you I wish to draw your attention to it without delay."

It appears, then, that the danger from milk, as far as the dairyman is concerned, is the introduction of specific germs through diseased cattle; and it is worthy of note that the liability to such disease is as great, if not greater, in cattle yielding rich milk than in those yielding poor milk. One of the reasons that sanitary officers have sometimes given for asking that the legal limits of milk shall be fixed above the average is that it will tend to "improve the quality of the dairy-cattle" supplying the city. Independently of the fact that it is no part of the sanitary method to develop superior types, it seems that such stimulation will lead to the worst conditions. Questions of chemic composition are trifling in proportion to the matter of the prevention of the spread of specific disease.

CORRESPONDENCE.

SCARLATINA AND MEASLES AT THE SAME TIME.

To the Editor of THE MEDICAL NEWS,

SIR: In THE MEDICAL NEWS of January 19th there is reported a case of scarlatina and measles in the same patient.

The following case came under my observation December 16, 1894: The patient was a little girl, five years old. She sickened two days prior to my visit, with scarlet fever of moderate severity. The exposure was some twelve days before. When the child was first seen the rash was well distributed over the entire body below the clavicles, and she presented a severe scarlatinal throat, with characteristic tongue; the papillæ being well elevated and the organ very red. The case advanced without any unusual occurrence, and desquamation began about the fingers and toes on the seventh day. My attention was then attracted by a cough which was due to a general bronchitis; the eyes were suffused, but I thought nothing of it until three days after the cough began, when a rash was then making its appearance on the forehead, the neck, and the face, having all the characteristics of that belonging to measles. On the following morning it covered the remaining part of the body, and was accompanied by lachrymation and coryza. No source of infection could be discovered and no case of measles existed in the neighborhood.

Very respectfully yours,

Herman C. Gordinier.

Troy, N. Y.

NEWS ITEMS.

Obituary.—Dr. Alfred L. Loomis, the distinguished physician of New York, died on January 24th, of heart-failure from pneumonia, after a brief illness. He was born in Bennington, Vt., in 1831, and was graduated from Union College in 1851, receiving his medical degree in 1853 from the College of Physicians and Surgeons of New York. Soon afterward he was appointed assistant physician to the charity hospitals on Ward's and Blackwell's Islands, and continued in this position for two years, when he took up private practice. In 1860 he became visiting physician to Bellevue Hospital, and later to Mt. Sinai Hospital, both of which positions he still held at the time of his death. From 1860 to 1875 he was consulting physician to the charity hospitals. In 1862 Dr. Loomis was made lecturer on physical diagnosis in the College of Physicians and Surgeons; in 1865, adjunct professor of the theory and practice of medicine in the University of the City of New York; and in 1867, professor of pathology. Dr. Loomis was a member of many medical societies, and was a generous contributor to medical literature. Among his more important works are *Lessons in Physical Diagnosis; Diseases of the Respiratory Organs, Heart, and Kidneys; Lectures on Fevers; Diseases of Old Age; A Text-book of Practical Medicine.* At his solicitation an anonymous benefactor in 1886 donated $100,000 to the University of the City of New York for the establishment and equipment of the Loomis Laboratory.

Dr. Loomis has bequeathed the income of $25,000 to the Loomis Laboratory; $10,000 to the Academy of Medicine for a Loomis entertainment fund, the income of which is to be devoted to the entertainment of Fellows of the Academy.

The Treatment of Variola with its Antitoxin.—Passed Assistant-Surgeon Kinyoun has reported to the Supervising Surgeon-General of the Marine-Hospital Service the employment of the blood-serum of a heifer calf, vaccinated four weeks previously, in the treatment of two cases of variola. Fifteen cubic centimeters of the serum were injected subcutaneously when the cases came under observation, and again after the lapse of eight or ten hours. In one case four injections were made, in the other seven. A careful study of the cases, individually and comparatively, led to the conclusion that the treatment exercised a modifying influence upon the disease, especially upon the eruption. One of the cases died, but it is believed that life was prolonged at least seventy-two hours by the treatment. It is suggested that as the serum appears capable of mitigating the attack of variola it ought to have the power of rendering susceptible individuals refractory to the disease.

ANALYSIS OF CASES OPERATED ON WITH THE AID OF THE MURPHY BUTTON UP TO THE PRESENT TIME.

BY JOHN B. MURPHY, A.M., M.D.,
OF CHICAGO;
PROFESSOR OF SURGERY AND CLINICAL SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS; PROFESSOR OF SURGERY, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON COOK COUNTY HOSPITAL; ATTENDING SURGEON ALEXIAN BROTHERS' HOSPITAL; CONSULTING SURGEON HOSPITAL FOR CRIPPLED CHILDREN, ETC.

A SUFFICIENT time has now elapsed to warrant a complete report of the cases operated on by means of the Murphy anastomosis-button and to justify us in drawing conclusions as to the field of its usefulness. The advantages and disadvantages of the device were at first theoretic; they were later sustained or controverted by the results of experiments and in a small number of cases; finally we have now a very large number of cases from which to draw conclusions, and a sufficient number, I believe, to enable us to make valuable deductions for our guidance in the future. We shall consider the cases in groups and endeavor so to arrange them that the danger of the disease for which the operation was performed will be about equal in individual cases of the same group. We shall pay particular attention to the fatal cases and endeavor to determine the cause of the fatality: whether it was a result (*a*) of the disease itself; (*b*) of the general condition produced by the disease; (*c*) of the operation; (*d*) of failure to obtain a perfect result at the seat of approximation; (*e*) of the sequel of the operation; or (*f*) of intercurrent causes. With this general plan as a guide we take up the subject as follows:

GASTRO-ENTEROSTOMY FOR MALIGNANT DISEASE.—By lateral approximation. Of this variety we have had twenty-seven cases with nine deaths. The first death was case No. 2. The patient had suffered from severe hemorrhage for four weeks preceding the operation, and it was hoped that by establishing a gastro-enterostomy a contraction of the stomach would take place, and possibly hemostasis. The operation was performed in seven minutes. The patient suffered little from shock, but the bleeding continued as before, and ended fatally four days later. The autopsy showed a perfect approximation. The second death was case No. 7. The patient died of exhaustion forty-eight hours after the operation. A perfect approximation was found on autopsy. The third death was case No. 9. The patient was very much emaciated and depressed before operation, and died twelve hours afterward. The autopsy showed a perfect approximation. The fourth death was case No. 15. The patient died of exhaustion in twelve hours. The fifth death was case No. 16. The smallest-sized button was used, as the operator had no other at the time. The button was so small that it was impossible for it to hold a sufficient amount of the tissue to retain the margin of a thick wall, as of the stomach, within its grasp. The wall slipped away from the clasp of the button, the gastric contents escaped into the peritoneal cavity and caused death. The smallest-sized button should never be used in any operation on the stomach. I do not consider it necessary to resort to the means suggested by Dr. Mynter and others, of placing a row of sutures outside of the button. If the proper-sized button be used and the running thread be properly inserted and tied, I consider the suturing unnecessary. The sixth death was case No. 17. The patient died of circumscribed peritonitis on the third day. On post-mortem examination the approximation was found to be perfect, and in the stomach was found a large ulcer three inches in diameter, which was probably the source of the infection. There was also carcinoma of the pancreas, the liver, and other organs, all of which contributed to lessen the resistance of the tissues against infection. The seventh death was case No. 21. The patient died of exhaustion four days after the operation. Perfect approximation was found, but no infection, and the button still in position. The eighth death was case No. 24. The patient died on the seventh day from a general suppurative peritonitis. Autopsy showed perfect approximation, and the button still in position; the cause of peritonitis was not given. The ninth death was case No. 26. The patient died of septic peritonitis. The button was not pressed tightly enough and an edge of the stomach had slipped away.

It will be noticed that four of the nine deaths resulted from exhaustion, two from imperfect operation, and three from peritonitis from infection at the time of operation. Are we justified in operating in these extremely emaciated, cachectic patients with carcinoma of the pylorus? What is gained by such an operation? The patients, as a rule, survive the operation but for a very short period of time, when they succumb to the marasmus of the disease and not to the effects of obstruction of the pylorus. It is my opinion (and my practice is in accordance with it) that patients who are not in condition to withstand a pylorectomy should not be operated upon. The relief obtained, even when gastro-enterostomy is successful, is so temporary that it does not justify the danger and discomfort of the operation, notwithstanding that the operation can be performed with the button in from five to seven minutes. These patients suffer much more from shock in operation than those with non-malignant disease, and the regenerative power of tissues in a patient with malignant disease is much impaired, *i. e.*, it takes a much longer time to regenerate the tissues in these cases than it does in patients suffering from inflammatory lesions. Therefore, in this class of cases I scarify with the point of a needle the surfaces of the peritoneum of the stomach and intestinal wall where they are brought in contact; this hastens the primary adhesions and increases the rapidity of definitive union. A few interrupted sutures, one-half inch from the button, between the intestine and stomach, may be necessary when there is great traction of the coil of intestine approximated, but I have so far not found a case in which I considered it indicated. I prefer the position of von Hacker, though that of Wölfler may be used. I believe, with Dr. Willy Meyer, that the former favors the passage of the button into the intestine.

If the carcinoma involves but a small portion of the stomach in the neighborhood of the pylorus, the most satisfactory operation in its ultimate result is a division of the duodenum two inches below the pylorus, closing the proximal end with a Czerny-Lembert suture and joining the distal end to the posterior wall of the stomach with the button. In non-malignant strictures of the pylorus this is the only operation that should be performed. When the approximation has been made to the anterior wall of the stomach, the button has dropped back into the stomach in four cases; in none of them did it occasion any unpleasant symptoms, and I believe it would have passed as soon as the stomach contracted to its normal size and the patient was up and about for a considerable time. In the case reported by Zielewicz (*Centralblatt für Chirurgie*, No 37, 1894) the port-mortem report shows conclusively that the purse-string suture was outside of the clasp of the button. Furthermore, "an enormous meal of liver-sausage" six days after a gastro-enterostomy, as was given this patient, was not conducive to success, although it was not certain that it had anything to do with the death. I have not used the oblong button for this operation, and do not consider it necessary, as the results so far prove that the opening made by the circular button is ample, and that the scar does not contract. It has, however, certain merits. It produces a larger opening; it is more easily inserted than the circular button, and passes through the intestine with greater freedom, as its diameter is only five-eighths of an inch. The only two cases in which it has been used are the following:

Case No. 29, reported by Dr. Joseph D. Bryant, New York. Diagnosis: fecal fistula of long standing. There had been several previous operations for its closure; it was believed to connect with the transverse colon. Operation was performed on May 9, 1894. Lateral approximation was made of the ileum to the descending colon with an oblong button (two-and-a-half inches in length); the button was easily inserted. Convalescence was uneventful. The button was passed on the fifteenth day. Dr. Bryant was the first to use the oblong button on the human subject. I am much pleased to know that the button passed at such an early day, as the oblong button causes a larger area of pressure-atrophy than the circular one.

Case 84, reported by Dr. Willy Meyer, of New York, was a male, aged twenty-two, who had a fistula in the right inguinal region. There was a history of appendicitis; the abscess was opened by a physician; a fecal fistula followed. Celiotomy was performed on May 31, 1894. Chronic appendicitis was found, and the appendix was imbedded in dense adhesions and perforated; resection of the appendix was performed; a loose tampon was inserted, and followed by the appearance of a fistula which baffled treatment. On August 16, 1894, ileo-colostomy was performed with the aid of Murphy's oblong button (two-and-a-half inches in length, five-eighths of an inch in width). The button worked like a charm. Its two halves could be tied in with great ease, and did not require a longer slit in the gut for insertion than the ordinary button. Recovery followed. The button was voided without any difficulty on the tenth day.

Conclusions.—1. Gastro-enterostomy should never be performed on an extremely cachectic patient.

2. The position of von Hacker is the preferable one.

3. A supporting suture outside of the button is not necessary except for the relief of tension.

4. In non-malignant stricture of the pylorus the end of the duodenum should be united to the posterior wall of the stomach.

5. Pylorectomy by the method to be described should always be resorted to when possible.

6. The patient should receive liquid nourishment immediately after the effects of the anesthetic have passed away.

Pylorectomy.—Pylorectomy is always the most desirable operation for malignant stricture of the pylorus, as it is the only one that offers hope of prolonging the life of the patient for a considerable time. When it is successful the patient regains his usual vigor and temperament rapidly, and is in good physical condition until the disease recurs. The period of immunity frequently extends over many months, and occasionally years. By the use of the button the operation of pylorectomy is relieved of its greatest dangers—of shock, as the time consumed in operation is very much lessened, and also of leakage at the seat of approximation. The operation is best performed in the following manner: *First*, ligate the mesentery on the upper side of the stomach, pylorus, and duodenum, as a broad pedicle, with from three to five double ligatures, and cut between; *second*, ligate the mesentery on the under side in the same manner. The pylorus can then be lifted well up in the abdominal incision; *third*, pack thoroughly around with gauze and place two clamps on the stomach, one above and the other below the place to be incised; *fourth*, a circular incision is then made in the stomach, including the peritoneum and muscularis. This is pushed back half an inch and the mucous membrane cut off; the latter is rapidly closed with a continuous suture; the serosa and muscularis are then closed with a continuous Lembert suture. Two clamps are placed on the duodenum, and it is incised; *fifth*, one-half of the button is then placed in the end of the duodenum and the other half in the posterior wall of the stomach, one inch from the line of suture, and pressed together. We had four operations of this kind reported, with three recoveries. In all of the latter the button passed on through the duodenum.

The first case was that of Dr. A. H. Ferguson, operated upon July 25, 1893. The patient is still living and in excellent health, having gained sixty pounds in weight. The second case was that of Dr. Willy Meyer. The patient died several months after the operation. The third case (No. 85) died five days after operation. The patient was in an extremely emaciated condition, and, while the operation lasted only forty minutes, he was in a critical state all the time until he died. The fourth case (No. 78) was reported by Dr. M. H. Everett, Lincoln, Neb. The patient, a male, aged thirty-five, first complained of stomach-trouble eleven years ago. He has never been free from pain since. Five years ago he commenced to vomit, and during the five years he had not passed a day without vomiting. He is a very intelligent man, and gave a fair history of his trouble. He believes that nothing had passed down from his stomach for four or five months previously to operation. He came under my charge in November, 1894. His stomach was very much distended, and there was a tumor perceptible at the pylorus. Operation was undertaken on December 18, 1894; the incision was in the median line and four inches in length; the tumor was drawn out; there were no adhesions; the tumor was as large as a small turkey-egg; the mesentery was ligated and divided; the stomach was incised one inch from the growth, and a Czerny-Lembert suture used; the duodenum was divided one inch from the growth; an incision in the posterior wall of the stomach was made, and the duodenum joined to it with the button. Certainly not five minutes were spent in making the anastomosis. The abdomen was closed without drainage; the temperature on the next day was 99° for a few hours, after which time it remained normal. The button was passed in two hours less than fourteen days after the operation. A wonderful change is noticeable in the man. He has not vomited, nor has he been nauseated. His appetite is enormous, and at this day, twenty-two days after operation, he has gained twenty pounds. The tumor was found to be a fibroma.

Cholecystduodenostomy.—The results of the operation of cholecystduodenostomy with the aid of the anastomosis-button have been most satisfactory. There have been thirty-eight operations reported for cholelithiasis, with thirty-seven recoveries and one death. In Case 26, the patient lived for seven days following the operation. There was a continuous hemorrhage from the laceration of the liver from separated adhesions. A large quantity of blood was found in the peritoneal cavity on autopsy; perfect union existed between the bowel and the gall-bladder, and there was no peritonitis. These results were obtained by twenty-two different operators. In my first article on this subject I recommended the removal of only a sufficient number of gall-stones to allow of the insertion of the button. I early abandoned this method, as I saw that it was possible for calculi to remain in the diverticula of the gall-bladder after the button had passed. That this opinion was well grounded was shown in case No. 2, which was referred to me by Dr. J. H. Hoelscher:

Operation was performed on August 19, 1892. The patient made an excellent recovery. The button was not found, and the patient's condition continued good until December, 1894, when she was again attacked with colic in the region of the gall-bladder. This was not accompanied by jaundice; neither were her attacks before the first operation. A cholecystostomy was performed, and two large calculi were found in a pocket at the upper end of the cystic duct. The gall-bladder, from the fundus down to the calculi, a distance of two-and-one-half inches, had contracted to a tube about the diameter of a lead-pencil. The button was not there, having evidently passed unnoticed; the stones were crushed and removed; the patient made an excellent recovery.

This is the only case in which there was a recurrence of the symptoms after the operation, and supports the view advanced in my original article, that the gall-bladder would contract to a tube, and that the opening between the gall-bladder and the intestine would become so small by the contraction of the gall-bladder that it would not admit feces into the tract. We have no case of infection of the liver or gall-tracts reported as a result of the operation. I believe, with Ruth, Willy Meyer, Ferguson, and others, and experience supports the position, that there is no danger from this source. A failure of union has not occurred in a single case. This is a most striking contrast in this particular to the results obtained with the suture. The theoretic objection expressed, that the button might drop into the gall-bladder and be retained there, has not been supported by a single case. The danger of hemorrhage in patients suffering from cholemia is very great ; many of them have purpura hæmorrhagica before the operation. The greatest precaution should be exercised in lacerating adhesions in this class of cases, as the hemorrhage may continue for days and even weeks.

The operations of cholecystenterostomy for malignant disease were very unsatisfactory, as there were eight performed, with seven deaths. Two died of shock, and one from twisting of the small intestine before making the approximation, producing a volvulus. In one case the gall-bladder was so friable from malignant disease that it tore like wet paper when the sutures were inserted, and after the button was placed in position and the abdomen closed the friable wall gave way and peritonitis ensued. In all of the others the approximations were found perfect on autopsy. While the mortality from the operation is great, not one of the deaths could have been attributed to the method. Still they all tend to show that the operation for malignant disease is not a justifiable one, and in many of my recent exploratory operations, when I have found a large carcinoma of the pancreas, duct or neck of the gall-bladder, I have abandoned the operation, and all of the patients have survived the exploration.

Cholecystenterostomy is contraindicated in gangrene of the gall-bladder. These cases should be opened and drained externally, and the peritoneum thoroughly protected by packing. The indications for the operation of cholecystenterostomy are :

1. Obstruction of the common duct.

2. Obstruction of the cystic duct, when cholecystectomy is impracticable.

3. Chronic cholecystitis, with thickening of the wall of the gall-bladder.

4. Fistula of the gall-bladder when the patient is emaciated from the loss of bile.

5. Carcinoma of the head of the pancreas in the early stage.

Intestinal Approximation.—It is in this field that the button has been of the greatest practical value. The pathologic conditions demanding its use in this class of cases greatly endanger the life of the patient. The cases may be well classified as follows:

1. Resection of the bowel for gangrene. (*a*) For internal obstruction ; (*b*) For hernia.

2. Resection of the bowel for cure of the fecal fistula.

3. Resection for malignant growths.

4. Resection for perforations of the intestine, both traumatic and pathologic.

5. Resection of the rectum.

Of the resections for gangrene of the bowel from internal obstruction we have fourteen cases and one death—case 64. The patient was a child that had suffered from a four-weeks' obstruction. She was so weak and emaciated when operated upon that she never rallied, and died in twenty-four hours. Of the resections for gangrenous hernia there were twelve, with two deaths. The first case, No. 4, died forty-eight hours after an operation for strangulated umbilical hernia which had perforated into the abdomen. A general septic peritonitis existed at the time of the operation. The autopsy showed continuation of the peritonitis, with perfect approximation, and the button in position.

The second case, No. 79, was a very interesting one, the patient having a congenital hydrocele of the testicle, with an inguinal hernia in a separate sac. The sac of the hydrocele connected with the sac of the hernia at its neck. The patient, after severe exertion, found his hernia down and painful. It was reduced in the usual manner, but the pain and vomiting continued. Six days after the obstruction occurred he was brought to me by Dr. Hanna, from Winfield, Iowa, who had seen him only a few hours before, and had made the diagnosis. I found the hernial sac free and empty, but a Littré hernia, involving four-fifths of the circumference of the bowel, was strangulated in the small opening of the hydrocele-sac. This knuckle had perforated into the sac, and the lining of the sac was gangrenous from the infection. A resection of five inches of intestine was made, together with an end-to-end approximation, the approximated intestine returned, and the abdomen dressed open. The patient's bowels moved six times within the next eight hours. He did not vomit, but his pulse increased in frequency, his facial expression became bad, and he died thirty hours after the operation, with all of the symptoms of auto-intoxication from the decomposing proteids that had been retained in the alimentary canal. There was no peritonitis. This case shows how important it is to act upon the symptoms of obstruction following an apparently complete reduction of a hernia.

Of resections for fecal fistula, with end-to-end approximation, there have been nine cases reported, all of which recovered. Here the results show that the operation of resection, with end-to-end approximation, promises much more for the patient than the lateral approximation, both for the immediate relief of the fistula and the permanent cure, and I now perform it in all cases in preference to the lateral. The relative value of the two operations is illustrated in case No. 45 in this report, and case No. 10 in the *Chicago Clinical Review* for June, 1894:

The patient had suffered for a period of two years from a fecal fistula, following a celiotomy for adherent ovarian cyst. It resisted all efforts at closure. An incision was made in the abdomen, and the two ends of the intestine which led to the fistula were approximated laterally with the button. The patient recovered nicely from the operation, but the fistula remained open. A plastic operation was done for the closure of the fistula, but it failed. The patient was continually emaciating, as the fistula was high up in the bowel. Nine months after the lateral approximation a second operation was performed. The fistulous tract was dissected out down to the peritoneum and ligated. A median incision was then made, and the adhesions of the intestine around the fistulous opening were separated, and the fistula and adherent intestinal coil drawn out of the abdomen. It was then found that two loops of the intestine were leaking at the seat of the fistula, and that only one loop had been relieved by the lateral approximation performed nine months previously. A resection of twenty-five inches of the intestine was practised, including both fistulæ, the entire adherent loop and the seat of the lateral approximation, and the bowel joined end-to-end with button No. 3. The patient made a rapid recovery. Four weeks after the approximation the button was found resting in the rectum. The opening made by the button used in the lateral approximation measured five inches at the time the specimen was removed, while the circumference of the button was only three-and-a-half inches, showing that the opening did not contract, but had expanded. (Expansion of the opening was also noticed in a case operated on by Dr. T. A. Davis, in which the specimen was removed several months after the operation.) The patient has increased in weight, and is now performing the duties of a domestic.

We have a total of forty-one resections for non-malignant disease, with two deaths. If to these be added the seven cases of Dr. Joseph Price, the details of which I have not received, with six recoveries, we have a total of forty-eight cases, with three deaths. The first death (case 4) resulted from continued peritonitis, the second death (case 79) from auto-intoxication. In Dr. Price's case the death occurred twelve hours after the operation, from shock. The operation consisted in the removal of an enormous universally-adherent fibroid, and the excision of several inches of bowel and a portion of one ureter. These results, obtained in the hands of many operators, certainly indicate that the question of operation in gangrenous hernia, internal obstruction, and fecal fistula, is definitely settled, *i. e.*, that resection with end-to-end approximation yields all that could be expected in the way of results.

Resection of the intestine, with end-to-end approximation, does not furnish as good results for malignant disease as for non-malignant, as is the case with all operations for malignant disease. Still, when we review and analyze these results they show a great improvement over those obtained by other methods, and are, on the whole, very satisfactory. There were thirty operations, with seven deaths. These include eight resections of the cecum, with one death. The cause of death in the malignant cases was as follows: In case No. 30, infection from without during the operation. A perfect approximation was found on autopsy. Case No. 35, from shock; death occurred ten hours after the operation. Case No. 56, from peritonitis. The specimen showed that there was no evidence of attempt at union at the seat of approximation, and that the peritonitis was present from the time of operation. Case No. 71 died of peritonitis. A specially large-sized button, one-and-a-half inches in diameter, was used. It fitted the intestines too snugly and produced a sloughing over the surface of the button, with perforation. In operations, as well as in experiments on the dog, this important factor should not be overlooked, that the button should fit easily in the intestine. Case No. 74 died of fatal peritonitis. The operator, in explaining the cause of the gangrene of both ends of the bowel, attributed it to the length of time that the ends were compressed during the operation, and this conclusion is certainly supported by the fact that both ends were gangrenous, that the perforation occurred, not at the seat of the pressure-atrophy, but beyond the margin of the button. If the gangrene had resulted from the button itself, it would have involved but one end of the intestine, and would have taken place at the position of pressure-atrophy, *i. e.*, at the junction of the button. The intestinal clamps that I use on the intestine, to prevent the escape of feces and gas, cannot produce this condition, as they do not compress the parallel artery of the bowel, which is surrounded by a cushion of fat in the triangle made up by the division of the peritoneal surfaces of the mesentery and the wall of the bowel. This artery is the most important one for the nutrition of the bowel, as is shown by my experiments on the intestine. In case No. 81 death occurred shortly after operation, but the cause was not reported. Finally in case No. 90 death resulted from exhaustion five days after operation. (See report.)

Resection for Perforations of Intestine, Traumatic and Pathologic, with End-to-end Approximation.—The mortality from perforations, both from gunshot wounds and for perforating ulcers, has always been very great, not that the danger resides in the operation for repair, but in the pathologic conditions themselves. Leübe, in his collection of 322 cases, found that when the operation was performed within twelve hours after pathologic perforation the mortality was 58.2

per cent.; if later than twelve hours, 79.5 per cent. In bullet-wounds of the abdomen the collapsed condition of the patient, the profuse hemorrhage, and the shock of the nervous system, all contribute very greatly to the mortality. The treatment of these cases, the practice of evisceration, now in vogue, to determine the number of perforations, and to be certain that none remain open, I consider excessive surgical precaution. We can estimate with great accuracy the position of the wound in the bowel by calculating the course of the bullet from the point of entrance to the position in which it is lodged. We are assisted very much in locating the bullet by the ingenious telephonic bullet probe of Dr. J. H. Girdner, of New York. The rule in bullet-wounds is that there are two perforations of the small intestine and none other, or two or more of the small and none of the large, or thirdly, the most common condition, there are a large number of perforations of the small intestine in close proximity, and, exceptionally, an additional perforation of the large intestine. This relation is accounted for, first, by the more or less irregularly transverse arrangement of the coils of the intestines, and, second, that a bullet rarely passes in the direction from head to foot, or the reverse. It more commonly passes either, first, from before backward, in which case we have one or two perforations; or, second, transversely, and we then have many perforations in close proximity, from three to fifteen in number, and situated very closely, *i. e.*, we may have as many as ten or twelve perforations within twenty inches of intestine. It is not necessary to eviscerate in order to locate them. They are in close proximity, and can be easily recognized. The operation should consist in resection of the entire perforated coil, an end-to-end approximation, with drainage of the cavity. When the perforations are a greater distance apart, double resections may be made and two buttons inserted, as in case No. 66, reported by Dr. R. R. Williams, of Manning, Iowa:

The patient was a male, sixteen years old. On August 7, 1894, he was injured by the bursting of a fly-wheel, rupturing the abdominal wall from the symphysis pubis to the umbilicus, the bowels protruding. Operation was performed six hours after the accident. On opening the abdominal wall it was found that a two-inch opening in the bladder existed, and the intestine was completely severed in two different places. The bladder was sutured. The bowel was united end-to-end with two Murphy buttons. The patient's convalescence was good except for extensive urinary infiltration. The buttons were both passed on the eighteenth day. The infiltration and necrosis continued, and the patient finally succumbed to the sepsis. This is the first successful case of double intestinal anastomosis with the buttons at one sitting.

Case 83.—For details of this very interesting case by Dr. F. H. Wiggin, see the *New York Medical Journal* of December 1, 1894. The operations for pathologic perforation of the intestinal tract are, as a rule, deferred too long. The profession has not yet extricated itself from the erroneous belief that the symptoms of collapse occur immediately after the perforation takes place. I would enunciate the following rule, and it should be impressed on the mind of every physician: *the manifestations of perforation into the peritoneal cavity depend upon the character and quantity of material admitted into the cavity and the pathologic changes produced thereby in the peritoneum.* By this I mean that the symptoms are not the result of the perforation *per se*, but the result of the pathologic changes produced by the result of perforation. To illustrate this law: In one case we will have a perforation of the intestine that will give rise to but slight symptoms of pain, nausea, discomfort, and local tenderness, but little elevation of temperature. This is the common train of symptoms produced primarily by a typhoid ulcer, and the symptoms may continue mild for a number of hours or days, even to a short time before dissolution, when symptoms of collapse occur. On the other hand, when we have a perforation of the stomach or the perforation of a peri-appendiceal abscess, the rupture of a pus-tube, etc., intense pain, great tenderness, nausea, vomiting, gulping, an anxious expression, a rapid thready pulse, and cold perspiration, take place more rapidly; but it should be distinctly understood that these are symptoms of pathologic changes in the peritoneum, and may not occur until a long period of time after the perforation has taken place, and are due to (*a*) extensive peripheral-nerve irritation, (*b*) toxemia, and (*c*) bacterial infection.

LATERAL APPROXIMATION.—There have been four operations of lateral approximation for malignant growths, with two deaths, and six for non-malignant disease; all of the cases recovered.

RESECTION OF THE RECTUM.—This operation has been relieved of its most trying mechanical part, *i. e.*, the difficulty of drawing down and approximating the upper to the lower segment, suturing it there and still retaining the sphincter intact. There have been reported three resections, with recoveries, and two lateral approximations, that is, approximations around the strictures with a pressure-atrophy of the stricture, a method in which the button is used, devised and described by Dr. Bacon in the *New York Medical Record*, December 10, 1892. The operation of resection, with removal of the sacrum (Kraske) and end to-end approximation with the button, was first done by Dr. Henry O. Marcy, of Boston, October 16, 1893. (Case 13, *Medical Record*, June 26, 1894.) The method of procedure for resection of the rectum is as follows: 1. In order to perform the operation without removing the coccyx or sacrum (Kraske), it is necessary to be able to reach the upper margin of the carcinoma with the index-finger. 2. The sphincter should be dilated until it is completely paralyzed; the carcinoma should be drawn down with forceps, and the rectum packed with gauze above. 3. A puckering-string should be inserted in and out through the wall of the rectum, one-half inch below the carcinoma, and left perfectly loose, so that the bowel may retain its entire caliber. 4. A circular incision is now made through the entire wall of the rectum, one-quarter of an inch above the suture and between it and the carcinoma. 5. The carcinoma and rectum are then liberated from the surrounding connective tissue, and the latter is drawn down as a cylinder into the lower segment of the rectum, and the separation continued until we are well up above the carcinoma. If the patient be a female, we shall find the cul-de-sac firmly adherent to the rectum, usually at the seat of the carcinoma. It should be cut open, the portion adherent allowed to remain, and immediately sewed with a fine catgut suture. The separation can extend up as far as necessary. One-half inch above the carcinoma another puckering-string is inserted, and a circular incision is made a quarter of an inch below this, cutting out the carcinoma. The gauze-packing is then removed. 6. The male portion of the button in which is threaded extremely heavy braided silk, double-drawn through the cylinder, is placed above, and the upper puckering-string tied around the cylinder of the button and cut short. The stem is held with a small forceps. (Do not use a heavy forceps to hold the button, as it presses the cylinder out of shape, thus preventing the button from closing.) 7. Slide the female portion of the button over the string, and press it up until it barely catches the end of the male cylinder, just sufficiently to hold. 8. Make a small parallel incision in the lower segment of the rectum over the coccyx and one-half inch below the first puckering-string inserted. Through this, pass a strand of iodoform-gauze for drainage outside of the button. (This may be removed on the third or fourth day, if necessary.) 9. Draw the button well down and tie the first puckering-string around the conjoined cylinders; cut the suture short and press the button together by making traction on the cord and pressing up from below. 10. Have the bowels loose before the operation, and keep them loose afterward, until the button frees itself, or can be liberated by slight traction about the tenth day. Use heavy silk both for the puckering-string and for traction-cords, as it is very unpleasant to have either break. Do not press the button too closely together before tying the second puckering-string. The traction-cords may be left in place until the button is removed.

CONCLUSIONS.—1. The cicatrix caused by the use of the button does not contract.

2. Size No. 1, ¾ inch, or 0.02 m., or No. 2, $\frac{13}{16}$ inch, or 0.022 m., should be used for cholecystenterostomy. I prefer No. 2.

3. End-to-end, side-to-side, and end-to-side approximation of the small intestine should be made with button No. 3, $\frac{15}{16}$ of an inch, or 0.025 m., in diameter.

4. End-to-end and side-to-side approximation of the large intestine should be made with button No. 4, 1 inch, or 0.026 m., in diameter.

5. A specially large size, 1¼ inch, or 0.029 m., in diameter, with a long male cylinder, may be used in some cases of resection of the rectum with advantage. But it should not be used unless it fits loosely.

6. In intestinal obstruction, resection, with end-to-end union, gives better results than lateral approximation, and should always be performed when practicable. The same operation should always be done in gangrenous hernia. In fecal fistula the bowel should be resected and united end-to-end.

7. The patients should receive liquid nourishment as soon as the effect of the anesthetic passes off. The bowels should be made to move as soon as possible after the operation, and frequent evacuations should be kept up.

8. If the button does not pass in three or four weeks, the rectum should be examined, as the button may rest just inside the sphincter.

9. There has been one case reported of occlusion of the button by fecal impaction in the cylinder. This can be easily avoided by a mild cathartic immediately after the operation.

10. When returning the intestines to the abdomen they should be placed in parallel lines, especially at the seat of approximation, to prevent sharp curves and obstruction. This occurred once with the button; many are reported following suture.

11. There is no danger of obstruction from the button, as not a single case has been reported. This proves that the deductions made by Choput, of Paris, from experiments on the cadaver are erroneous.

12. There is no danger of extension of the pressure-atrophy beyond the line of pressure.

13. Primary adhesion may be hastened in malignant cases by abrading the peritoneum with a needle. It is unnecessary in non-malignant cases.

14. A supporting suture is never necessary to secure union, and should only be used to relieve tension when the viscera approximated are forced out of position.

RESECTION, END-TO-END APPROXIMATION. (METHOD: MURPHY BUTTON.)

23	Sept. 26	Med. Week., Paris, Oct. 13, 1894.	Jaboulay.	Carcinoma of pylorus.	Gastroenterostomy.	L.	R.	…………	Button No. 3 used, which passed on 14th day. Patient made an excellent recovery.
24	Aug. 23	Cal. Med. Journ., Nov. 18, 1894.	Case, C. E., Tacoma.	Carcinoma of pylorus.	Gastrojejunostomy.	L.	D.	Peritonitis, 7 days.	Autopsy: perfect union at seat of approximation; button still in position; general suppurative peritonitis.
25	1893 Oct. 12	Not published.	Griffith, J. D., Kansas City.	Carcinoma of pylorus and duodenum.	Gastrojejunostomy.	L.	R.	…………	Died two weeks later of exhaustion. Patient 72 years old, and very much emaciated.
26	Nov. 10	" "	Griffith, J. D., Kansas City.	Carcinoma of duodenum and liver.	Gastrojejunostomy.	L.	D.	Septic peritonitis.	Button not pressed tightly enough, one edge loose; patient 60 years.
27	1894	Paris Week, Jan. 4, 1895.	Monod, Paris.	Carcinoma of pylorus.	Gastroenterostomy.	L.	R.	…………	Button voided on 12th day. Doyen's procedure approximating intestine to posterior wall of stomach through perforation in transverse mesocolon.

15. The mucous membrane should be pushed down in the cup of the button before closing it; if redundant, it should be trimmed off with the scissors. *It should never be allowed to protrude between the edges of the button when the button is closed.*

16. While the button is easily inserted, the pathologic condition requiring the operation may demand the greatest surgical skill to secure a favorable result.

17. The following points regarding the construction of the button should be noted before using it:

(*a*) The spring catches should hold firmly in all positions and should be made of a metal that will not be corroded by acids.

(*b*) The elastic-pressure cup should be on the male half of the button (never on the female).

(*c*) The edges of the pressure-surfaces should be very smooth and hemispherical in shape.

(*d*) The spring under the pressure-cup should not be too strong.

(*e*) There have been defective buttons on the market. The following firms are at present manufacturing perfect buttons: J. J. Ryan & Co., Chicago; Truax, Greene & Co., Chicago; Geo. Tiemann & Co., New York; W. F. Ford & Co., New York; Down Brothers, London, England; Sharp & Smith & Co., Chicago; Frantz, Kratzmüller & Co., Chicago and Berlin.

18. If the button appears at the opening of the fistula after lateral approximation, do not try to force it through the opening; this is unsurgical. Open the abdomen, and (*a*) press it back to the anastomotic opening and through it on down the intestine, and it will pass; or (*b*) make a longitudinal incision in the bowel and take it out.

PHYSIO-MEDICALISM.

BY J. BEN NICHOLS, M.D.,
U. S. SOLDIERS' HOME, WASHINGTON, D. C.

PHYSIO-MEDICALISM, also called sanative medicine, is a descendant of Thomsonian or botanic medicine, and arose in Ohio about 1845, having continued to the present time as a weak and rather obscure medical sect, the only surviving form of Thomsonism in America.

Alva Curtis, who formulated and developed physio-medicalism from the Thomsonian system, was born in New Hampshire in 1797. He obtained a good general education (receiving late in life the degree of A.M.), and studied medicine for a time under a preceptor. Up to 1832 his main occupation was teaching; but after the cholera-epidemic of that year he engaged exclusively in practising and disseminating the Thomsonian medical system. About 1837 he became editor of a Thomsonian journal, and gave instruction in the system at Columbus, Ohio. In 1839, under a State charter, he established the Botanico-medical College of Ohio, which in 1841 was transferred to Cincinnati. He continued editor of the journal until 1855, and taught in the college until 1875. During that time he wrote numerous works in presentation and support of physio-medicalism, some in a style of tedious pseudo-philosophic analysis, some of a controversial character. He died in Cincinnati in 1881.

The Physio-medical College of Cincinnati, founded by Curtis, in 1839, as the Botanico-medical College, and under his management for many years, was the leading influence in the promulgation and maintenance of the system. The name physio-medical, which was introduced by Curtis about 1842, was applied to it from about 1849. The institution continued in existence until 1880. Other physio-medical schools have existed, at Cincinnati, from 1859 to 1885; at Marion, Indiana, from 1881 to 1890; at Indianapolis, since 1873; and at Chicago, since 1885.

The leading physio-medical periodical, the *Recorder*, was established in 1832 as an exponent of Thomsonism, and was one of the first journals devoted to that system. It was entitled the *Thomsonian Recorder* up to 1837, the *Botanico-medical Recorder* from that date until 1852, the *Physio-medical Recorder* after that until, consolidating with another journal, it appeared as the *Cincinnati Medical Gazette and Recorder* from 1880 to about 1885, when it became extinct. The successive changes in name correspond to changes in Thomsonian thought.

W. H. Cook, another leading exponent of the system, succeeded Curtis as editor of the journal in 1855. Besides this, the sect has had one or two journals which were short-lived, and the two existing periodicals, published at Indianapolis, Indiana, and Westerville, Ohio, since 1875 and 1891 respectively. Besides its journals, the literature of physio-medicalism consists mainly of the writings of Curtis and a few works by Cook and recent authors. Illiteracy, shallowness, and narrowness are a pervading feature of its periodical literature and modes of thought.

Physio-medicalism at the present time has its greatest strength in Ohio, Indiana, Illinois, and Iowa, with some following in the States adjoining them, and in Texas, Oregon, and Washington; between two-thousand and three-thousand practitioners are claimed for it in all, but this is probably an excessive estimate. There is a national association of its practitioners, organized in 1883, which has about 150 members; State organizations exist, in a condition of more or less vitality, in Indiana (organized in 1863—the oldest existing physio-medical society), Ohio, Illinois, Iowa, Michigan, and Washington.

The sect now has two journals and two colleges; the number of graduates from 1881 to 1890 averaged 21.6 annually, but since then the number appears to have diminished more than one-half.

The characteristic fundamental doctrines and claims of physio-medicalism are as follows:

Professing to reject speculation and human assertion and authority and to be free from human error, physio-medicalism claims to be based solely upon and guided solely by the "immutable" teachings and laws of nature, wherefore it considers itself infallible. This idea is represented in the name physio-medicalism, which is taken to mean "natural medicine," that is, medicine taught by and following Nature.

Disease is viewed as a disturbance of the normal action of the vital principle. All diseases are looked upon as essentially the same in their general nature—an inability of organs to perform their natural functions properly, owing to the derangement of the vital action. The vital power, or nature, is a potent curative agent, and powerfully resists disease and promotes recovery. Physio-medicalism (as the name partly signifies) professes that its fundamental therapeutic principles are to aid and follow Nature.

The pathologic notion upon which physio-medicalism lays the greatest stress is that fever, inflammation, irritation, etc., are not diseases or injurious to the organism, but that they are manifestations of vital efforts to cure disease, and should be aided, never opposed, by medication. The great error of regular medicine, from the physio-medical standpoint, is the idea that fever is destructive and injurious, not recuperative, and the antipyretic treatment based on that idea.

All drugs are considered to be divided into two distinct and sharply-defined classes—those that oppose and those that aid the vital force and vital processes. The former are the poisons, which destroy the tissues and, in sufficient quantities, life itself; they are always injurious, and should never be used in the treatment of disease; since they cause disease, it is absurd to suppose that they can ever cure it. The drugs of the second class are gentle, innocuous, and always beneficial, never injurious; their action is always to tend toward and vanish in health; they are the only true remedies for disease, and they alone should be used in treatment. These are called "sanative" medicines, a designation often applied as a name for the whole system. The injuriousness or harmlessness of a substance is an essential, unvarying characteristic; a poison, for instance, is always a poison, injurious under all circumstances and in every dose. Physio-medicalism expresses firm opposition to the use of powerful agencies like bleeding, mercury, opium, and similar active means.

Although only innocent medicines may be used, there is no restriction to vegetable substances. While the physio-medical materia medica comprises many articles, the principal remedies are lobelia, capsicum, and the vapor-bath. "Courses" of medicine are also prescribed, by which, it is claimed, "any sensible man or woman" can cure nine-tenths of all diseases. Superior results are of course claimed by physio-medicalism from the treatment of disease on these principles.

The correspondence of these methods and doctrines with those of Thomsonism is marked. Physio-medicalism is a descendant, somewhat refined and modified, of Thomsonism, with some of its notions adapted or dropped, and a few principles that had only a minor place in the earlier system worked out to greater prominence. Physio-medicals, while considering that the Thomsonian system contained some crudities, errors, and even absurdities, of minor importance however, regard the system as of general excellence, and honor Thomson as the discoverer of (alleged) true and revolutionary medical principles.

In estimating the merits of physio-medicalism, a system originally derived from the teachings of Samuel Thomson, the latter's utter lack of education and experience and the commercial character of his operations should be borne in mind.

The claim of being so founded upon the teaching of nature as to be infallible and free from human error is idle. The same claim is put forth for all dogma, and the same object is aimed at by true science and philosophy as well. All the facts and laws of nature have to be laboriously searched out by human observation and interpreted by human intelligence; all investigations of truth are subject to the same fallible human element. It is therefore pure assumption for the physio-medicals to claim to know the operations of nature beyond the possibility of error or to have a method of pursuing knowledge superior to all others.

The position of physio-medicalism upon the pathology and treatment of fever, its chief point of antagonism with regular medicine, does not stand the test of facts as a universal truth. In some cases of fever and inflammation, it is true, diaphoretic and relaxing treatment is proper and effective. But it is equally true that in other cases vigorous antipyretic treatment by drugs, and especially by cold baths, is capable of producing marvellously beneficial results. This is so well established as to be beyond denial. The indiscriminate rejection of antipyretic treatment, according to the fixed blind dogma of the physio-medicals (however applicable it may be in a few cases), is manifestly wrong and contrary to the interests of the patient.

The doctrine that poisonous drugs are always injurious and curative drugs always innocuous cannot be true. There are many drugs, like quinin, strychnin, arsenic, and alcohol, that are markedly curative and beneficial in proper doses, but are violent poisons in larger quantities. It is, in fact, their powerful properties that render such drugs effective and make many of them among the most valuable of remedial agents.

Aside from this principle as a theoretic abstraction, the practice of using gentle and agreeable medicines is highly commendable and important. Physio-medicalism has no monopoly of such treatment; the prevailing use of lobelia in its practice is, in fact, far from being of such safe and gentle character as is desirable.

There is great inconsistency between the teachings of physio-medicalism concerning poisons and its use of lobelia. The adherents of the system deny that lobelia is, under any circumstances, poisonous; they are indignant that the drug is asserted to be injurious and because dealers sell it labelled "poison"; and they laboriously attempt to explain away the damaging facts and fatal cases against it. They cite, as an argument for the harmlessness of lobelia, instances in which large doses have been taken without injurious results, which is equal to claiming that it is perfectly safe to fall from the top of a high building because cases have occurred in which persons have not been injured by such falls. All their claims cannot diminish the fact that lobelia is a harsh, depressing drug and a powerful poison. Numerous fatal cases of poisoning by it are on record; the Thomsonian medical systems are responsible for many deaths occasioned by its use, and botanic practitioners have been repeatedly tried and convicted for fatal results so caused.

The system is bred and sustained by extravagant enthusiasm and exaggeration of the importance of one or two minor ideas, with consequent disregard and rejection of other elements which are also included in the aggregate of truth; such factors flourish most in narrow and ignorant minds. The verdict of the world upon Thomsonism has been passed and the sentence of extinction has been executed. Its offspring, physio-medicalism, languishes, weak and obscure; and it is doomed eventually to be swept away as a stain that smirches a small corner of the edifice of truth.

THE SALOL-TEST FOR GASTRIC ATONY.

By A. L. BENEDICT, A.M., M.D.,
LECTURER ON DIGESTIVE DISEASES, UNIVERSITY OF BUFFALO, DENTAL DEPARTMENT.

There are a number of organic chemicals that are insoluble in an acid medium and that break up into two components in the presence of an alkali. Salol, a union of salicylic and carbolic acids, is the best known of these, and it has been employed to mark the time of the passage of the stomach-contents into the intestine. A powder of salol is given at the end of a meal, the urine is saved at, say, fifteen-minute intervals and tested for salicylic acid by pouring a few drops of liquor ferri chloridi into the test-tube. The formation of ferric salicylate is indicated by a dark, permanganate color. A gram is usually given, but as a few deaths have occurred from this or a slightly larger dose, it is better to give half a gram. The test should be found in from forty-five to sixty minutes after the ingestion of salol.

It is plain that the salol-test cannot indicate the real emptying of the stomach, but only the preliminary leakage through the pylorus. Again, the time set as an average includes the decomposition of salol, the absorption of its components, their passage through the portal (or possibly the lymphatic), pulmonary, and systemic vessels to the kidneys, and their elimination and passage through the entire urinary tract. Judging by the potassium-iodid test for gastric absorption, about ten minutes must be subtracted for these various delays. It must also be considered that the change in reaction is not an instantaneous one. In animals the reaction of about the first eighteen inches of the intestines is acid. However, if it could be established that in spite of these *à priori* objections the normal time of the appearance of the salicylic test were considerably increased and diminished by atony and irritability, respectively, of the gastric muscles, the test would still be of practical value. Relying on the reputation of the advocates of the test, I have used it for some time, until the surprising monotony of the results led to neglect and finally to a more careful recording of notes to learn if my growing skepticism was justified. It is regretted that earlier and much more numerous memoranda were not saved. Still, they would only have added force to the present list.

In this series of nineteen observations the average time for the appearance of a marked reaction (without extracting with ether) was fifty-five minutes, the minimum thirty, and the maximum ninety. These extremes were reached in two persons each. All four were afflicted with sub-acid or non-acid dyspepsia, shown by chemic examination, except in one minimum case, a feeble old woman who had chronic bronchitis. Of course, the chemic examinations were not made after the same meal as the salol-test, so that absolute conclusions are out of the question. It is also probable that the maximum is in excess of the true time, for the seventy-five-minute urine was not saved, and in one case there was already a slight reaction at the end of one hour. With observations fifteen minutes apart, and the extreme limits only an hour apart, the word *average* loses much of its significance. It would be better to say that the three-quarter-hour and the one-hour samples were those in which salicylic acid was usually found (fourteen times in nineteen examinations); that a slight or even a marked test might be found in the half-hour sample; and that the hour-and-a quarter sample should always show the reaction.

A control-experiment made in a healthy man is of the highest interest. I argued that if the salol-test was of any value in showing the time of the emptying of the stomach, it would appear more quickly if given when the escape of chyme through the pylorus had already begun. Fifteen centigrams of salol were given an hour-and-a-half after a meal, and the urine saved every ten minutes. At twenty minutes there was the merest darkening of the urine on adding ferric chlorid. At thirty minutes there was a trace of salicylic acid; at forty minutes a good reaction. Thus, with the stomach presumably already emptying itself, the elimination occurred only fifteen minutes earlier than the average of the series, and not so early as in several instances when it was given immediately after the meal. The period of elimination in this case occupied about thirty-six hours.

The decomposition of salol was, by Ewald, attributed to the pancreatic secretion, but Gley, by removing the pancreas from two dogs, showed that the decomposition still occurred. Stein's experiments have shown that mucus accelerates the absorption of salol, and that it may be absorbed from the stomach. Case XII illustrates this point, for the patient swallowed considerable mucus if, indeed, there was not true gastric catarrh. Cornet states that an hour-and-a-half is required for the appearance of salicylic acid in the urine, which is certainly not true clinically. He also states that salicylic acid may be found in the stomach two or three hours after large doses of salol. His experiments, however, were made on healthy animals, and the present series of cases seems to indicate that in sub-acid dyspepsia salol is decomposed much more rapidly in the stomach, unless we assume that persons with secretory failure have an excess of muscular activity on the part of the stomach. Case III, with a moderate amount of hydrochloric acidity, had a very slow digestion, food remaining in the stomach six or seven hours after a medium-sized meal, but the salol-test occurred an hour after eating.

Cornet states that after fifty centigrams of salol, elimination requires at least twenty-four hours. Huber considers it a sign of atony if more than twenty-four hours is required. In Case VII, in which a faint reaction was seen in the one-hour sample, and good tests in these one-and-a half and two hours after the meal, salicylic acid was absent in the three-hour sample. Unfortunately later tests were not made. Cases XII and XVI, in which, according to the ordinary test, gastric motility was good (salicylic acid being found half an hour after the meal), showed the reverse condition according to Huber's method, since elimination required, respectively, thirty-six and forty eight hours. Judging from the clinical appearances, Case XII was much the more atonic of the two; in fact Case XVI recovered very rapidly. It would seem that the duration of elimination would depend largely on circulatory, and especially upon renal conditions, so that Huber's test would not be decisive as to gastric atony.

It will be observed that while this series, in a general way, seems to show that achlorhydria may allow the quite rapid absorption of salol from the stomach, there are enough discrepancies to vitiate any possible value that the test might have in this direction. In fact, the conclusion seems justified that the appearance of salicylic acid after the administration of salol merely means that the latter has been absorbed somewhere, and that no practical deduction can be drawn, unless possibly from the occurrence of a very marked delay, but this delay does not often occur in the very cases in which we should most expect it.

Cases.

		Hours.	Hours.	Hours.
I.	*Hepatic cirrhosis, gastric catarrh*	½	¾	3
II.	Hepatic cirrhosis, stomach nearly normal	..	1	1½
III.	Incipient pulmonary tuberculosis(?), *subacidity, fermentation acids, slow digestion*	...	1	
IV.	*Incipient pulmonary tuberculosis*, subacidity, and atonicity	¾	1	1½
V.	Subacidity with *eructations*	...	1	3
VI.	*Slight dilatation, eructations*	½	¾	
VII.	*Subacidity** and atonicity (Jan. 13)	...	1½	2
	No salicylic test 3 hrs. p.c. (Apr. 1)	...	1	2
VIII.	Subacidity	¾	1	
IX.	*Subacidity*	½	35 min	
X.	*Subacidity**	½	¾	2

XII.	*Chronic bronchitis*, gastric catarrh(?)	...	½	1¼
XIII.	Atonic dyspepsia (subacid)	...	1	1½
XIV.	*Subacidity** (Oct. 30)	½	¾	3
	Marked *butyric acid* (Oct. 31)	...	1	3
	Fermentation (Nov. 13)	...	¾	
XV.	*Subacidity**	½	¾	
XVI.	*Subacidity**	...	½	

Note.—Diagnoses in *italics* were verified by physical and chemic examination. Cases of subacidity, marked with a star, showed absolute lack of hydrochloric acid.

The first column, marked "hours," refers to the finding of slight traces of salicylic acid after extracting the urine with ether. The second column indicates the time at which a marked reaction was first found. The third column refers to the time at which the qualitative reaction appeared most marked in the urine saved at intervals up to three hours.

CLINICAL LECTURE.

TUMOR AT THE BASE OF THE BRAIN.[1]

By CHARLES CARY, M.D.,
OF BUFFALO, N. Y.;
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, UNIVERSITY OF BUFFALO.

This young woman presents a number of symptoms that will enable us to make an unerring diagnosis of a disease that, on account of its gravity, I am glad to say, is comparatively rare. She tells us that she was born in this country, is twenty-three years old, unmarried, and that her family has been exceptionally healthy. In childhood she had scarlet fever, diphtheria, and several of the milder infantile disorders that left her without sequelæ; her health since childhood until about a year ago was good. Last January or thereabouts she began to have headache, a trouble previously unknown to her, except occasionally as an accompaniment of menstruation. It persisted, became more grave until the slightest pressure on the head caused the greatest distress. You will notice from her expression that the finger barely touching her forehead induces a jar that is extremely painful. After the headache had lasted for two months or more it was aggravated by persistent vomiting. The vomiting was unaccompanied by nausea, was without abdominal pain, and no alterations in the diet relieved it. For over nine days she vomited almost incessantly. About this time, about the first of April, she became suddenly paralyzed, and for two days was unable to speak. We have not the benefit of the results of an examination at this time, and cannot determine the actual extent of the paralysis. Her statements seem to limit the paralysis to the face. When I ask her to go through the various facial movements, such as smiling, raising the eyebrows, attempting to whistle, you see that there is no apparent paralysis present. But the use of this pin-point shows that the sensibility of the left side of the face is decidedly impaired, and the finger can be brought in contact with the outer canthus of the left eye and with the conjunctiva without producing the marked reflex movements that it does on the right side. Even the left nostril seems to be less susceptible to sensory impulse when she inhales this strong vinegar or ether. Pursuing the investigation further, see how different is the appearance of the mucous membrane of the mouth on the two sides. Note the sponginess of the gum on the left side and the accumulation of food between the cheek and the teeth, of which she seems to be unaware. Compare with this the right side, where the mucous membrane is wholesome, paler, and much more cleanly. She tells us also that she does not chew with the left side of her jaw, and as I invite her to bite upon a lead-pencil, you can see that there is a partial paralysis of the muscles of mastication on the left side. There is loss of sensation as well as of taste upon the left side of the tongue, and paralysis of the left hypoglossal nerve, as shown by protrusion of the tongue to the left. As I look closely at her eye I see that there are one or two hairs and some particles of dust on the conjunctiva, to which she seems indifferent. The mucous membrane is engorged and in a state not unlike that of the mouth and nose. This condition of the eye followed her sudden paralysis in April. When I ask her what the next occurrence was, she tells me that her eyes began to weaken and that vision failed, so that for four or five weeks she has been totally blind in both eyes. As you see, when I shade her eyes and then suddenly expose them to light, there is no pupillary reflex. There is a general paresis of the left eye, so that, asking her to follow the snapping of my finger with her eyes, the right eye moves much more freely than the left. Personally I have not examined the fundus of the eye, but a report from Dr. Lucien Howe states that she has extreme atrophy of both optic nerves, with retinitis in the left eye.

There is but one other point in the general appearance of the patient to which I wish to call your attention, and that is the facial expression, which, except for the manifestation of pain in the frontal corrugation, is one of apathy. Her attitude when not disturbed is one of sluggish indifference. At each of my visits, and I have now seen her a number of times, she has been listless, apathetic, sitting in one position for a long time unless invited to some occupation. Her statements have not been to the same effect at all times, and the discrepancy I ascribe not to any untruthfulness but to a failure of memory. As recorded in the hospital-book, she told us, at the time of her admission, of two distinct convulsions that occurred in April. To-day she has omitted to mention them.

I believe that we have here a case of intra-cranial tumor. From the involvement of so many nerves, it must be located at the base of the brain, where, from pressure on nervous tissue, from venous obstruction, and from consequent increase in the cerebro-spinal fluid, it has produced the various symptoms present. These symptoms are divisible into two groups, the focal, which enable us to locate the seat of disturbance, and those that are due to the change in intra-cranial pressure. Neither of these groups of symptoms will aid us directly in diagnosticating the kind of tumor.

The most characteristic symptom of increased intra-cranial pressure, and, therefore, of brain-tumor in general, is the constant headache coming on in a person not subject to such trouble and without other assignable cause. Any jar of the head increases the pressure momentarily, and, as you have plainly seen, aggravates the pain. This same increase of pressure produces the mental dulness, which is a very fortunate circumstance, as the suffering and realization of the condition are thus materially lessened. The same increase in intra-cranial fluid has caused prolonged pressure on the optic nerve, with resulting atrophy, as indicated by the loss of vision. Even this candle, placed close to her face in different positions, induces no retinal impression. You will note that the loss of vision is not a focal symptom, as it is general and complete. A hemianopsia would point to pressure upon one optic nerve. The vomiting, of a projectile nature, we may also believe to be purely a pressure-symptom. The epileptiform convulsions—granting that she had them—must also have been pressure-symptoms.

The left retinitis and conjunctivitis are due, not to atrophy of the second nerve, but to that of the ophthalmic branch of the fifth, in which is located the trophic control of the eye.

---

[1] Clinical Lecture at Buffalo General Hospital.

The impaired sensibility of the face, tongue, and mouth, as well as the loss of taste, points to the involvement of the fifth nerve ; the motor nerve of the face, the seventh, has been involved, according to the history, but at present the paresis is limited to the tongue, supplied by the hypoglossal, and to the muscles of mastication, supplied by the inferior maxillary division of the fifth. The impairment of the sense of smell is, I believe, explained by the trophic changes in the mucous membrane, due to the involvement of the trifacial nerve. The lesion must, therefore, be at the base of the brain, on the left side, but not extending far outward, as the seventh, eighth, ninth, tenth, and eleventh nerves escape. The tumor must lie in the posterior part of the middle fossa of the skull, extending, perhaps, into the anterior part of the posterior fossa. Its exact localization is only a matter of analytic interest, inasmuch as a basal tumor cannot be operated upon, and it is only in cases in which surgical relief is possible that the anatomic location is important.

Of the several kinds of tumor that may occur in the cranium, I believe that this is most probably a sarcoma, as such growths are more liable to be basal, or it may, perhaps, be tuberculous. It has undoubtedly originated in the fibrous tissue at the base of the brain.

In the hope that the tumor might be syphilitic the patient was placed upon specific treatment, but the heroic doses of potassium iodid that she has taken have failed to afford relief. This treatment has, however, had a diagnostic value. The principal treatment now is directed toward the relief of the more troublesome symptoms. The loss of sensitiveness in the left eye, which has already allowed foreign bodies to set up a conjunctivitis, may result in the formation of an actual ulcer. Washing with rose-water and boric acid will benefit this, and the application of a patch over the eye may be necessary if her indifference to injuries threatens its destruction. Her headache has been in a measure relieved, and I should advise the continuance of the treatment by the use of salines to deplete the system, and, so far as possible, to diminish the intra-cranial pressure. There has been no vomiting since she entered the hospital; and her headache, though persistent, has been so much milder that it has not caused intense suffering. We have a right to expect nothing more than to be able to keep her in a comfortable condition.

The end of the case may come through cerebral hemorrhage, which has already once occurred, to judge from the sudden paralysis, or an aggravation of the pressure from the simple growth of the tumor may induce a retarded pulse and respiration, followed by coma and death. If the nature of the tumor be tuberculous, meningitis may result and cause death, with the ordinary symptoms of that disease.

Fatal Poisoning by Quassia.—Venn (*University Medical Magazine*, vol. vii, No. 4, p. 304) has reported the case of a child fatally poisoned by a rectal injection of a decoction of two ounces of quassia in about a pint of water, made for the relief of seat-worms. From five to ten minutes after the injection the child became livid, vomiting took place, the muscles became relaxed, and respiration labored and shallow and the pulse imperceptible. Death took place within a few minutes.

CLINICAL MEMORANDA.

ON CERTAIN MORPHOLOGIC AND MICROCHEMIC PECULIARITIES OF THE BLOOD IN DIABETES AND GLYCOSURIA.[1]

BY LUDWIG BREMER, M.D.,
OF ST. LOUIS, MO.

When we look back on the development and progress of the medical sciences during the last forty or fifty years, and consider the amount of minute and exact information which during that time anatomic investigation has furnished about the tissues of the human body, it seems strange that we are still in the dark about the anatomy, both normal and pathologic, of that tissue upon which all the others depend, the blood. Hematology is the most neglected of all the branches of medicine. Possibly this neglect has been due to the trend of medicine during the past four or five decades, which eschewed humoral pathology and, so to say, looked with contempt upon the blood.

It is only of late, say in the last fifteen years, that the interest in this most important, because health- and life-sustaining, tissue has been revived. A powerful impetus in this direction was given by the discovery of the plasmodium malariæ, which in its turn was the result of the bacteriologic tendencies of modern medicine. The methods invented for the study of bacteria were applied to that of the blood, but principally for the purpose of finding and demonstrating the pathogenic microbes coursing in the circulation. The changes that these microörganisms might produce on the cellular elements of the blood did not seem to enter into consideration on the part of the investigators.

With the discovery of the plasmodium malariæ the attention of the pathologist was once more directed to the much-neglected and almost entirely-disregarded red blood-corpuscle, in which the parasite named is found in cases of malarial fever. Ehrlich's demonstration of the various granulations of the several kinds of white blood-cells was another stepping-stone on the road to substantial progress, at least so far as the histology of the blood in the normal state is concerned.

At the present time, it may be said, the most rudimentary methods of blood-investigation still prevail, and beyond the counting of the red and white blood-corpuscles, the determining of their relative numbers, the demonstration of the specific granulations, and of the amount of hemoglobin, very little is known. The changes in the red blood-corpuscles in anemia, poikilocytosis, and microcytosis are also very incompletely known, owing principally to the fact that our knowledge of the normal histology of the red blood-corpuscle, which in the course of this article I shall for brevity's sake call erythrocyte, is extremely defective.

For a number of years I have been engaged in the study of the corpuscular elements of the blood in health and disease ; the results of these investigations, constituting, in my opinion an attempt, though possibly a feeble one, at a systematic pathologic anatomy of the blood, I shall publish at no distant day. One of the results of my work on this subject I shall now briefly describe. It is an observation which I have made on certain morphologic and microchemic properties of the blood in diabetes and glycosuria.

---

[1] Read before the St. Louis Medical Society, January 19, 1895.

It is hardly necessary to state that any contribution to the knowledge of a disease like diabetes, which has been studied so much and explored so little, so far as tangible results are concerned, must be a welcome addition to the stock of our knowledge. It is also plain that even the smallest step in the direction of ascertaining the nature of so obscure a disease may become one of the stations which are constructed along the road leading to the goal of all medical study, the cure of the disease.

It is well known that the blood in the physiologic state contains a certain percentage of sugar, whose amount varies between 0.1 and 0.3 per cent., and that 0.15 is probably the average percentage in normal blood. Traces of it, as is also well known, occur in the urine of healthy persons, but are not demonstrable with the usual chemic tests, say, Fleming's and Nylander's. A positive result with these reagents excites at once suspicion of metabolic disturbance in the individual from whom the urine has been obtained. Now, the essence of my discovery lies in the fact that whenever sugar can be demonstrated by the usual methods, either by the ordinary chemic tests, or by the polariscope, or by fermentation, there is a distinct and characteristic color-reaction of the erythrocytes on the application of a microchemic test by a combination of certain anilin colors. The method which I have employed for this and other purposes is as follows:

Two aqueous solutions of eosin and methylene-blue are made, viz., from 24 to 28 drops of a 0.5 per cent. solution of eosin are added to 2 drams of a saturated solution of methylene-blue. With these proportions the neutral boundary is approximately obtained, where the reaction is neutral, neither acid (eosinophilious) nor alkaline (methylene-blue reaction). This neutral point is determined by dipping a small piece of white filtering paper into the solution. There is, when exact neutral reaction exists, scarcely any coloration of the paper slip, or at most a very faint grayish-blue tint. To one-half of this solution in a watch-glass a drop or a fraction of a drop of the 0.5 per cent. eosin-solution is added, just enough to show a decided preponderance of the eosin stain, recognizable by the red color of the paper slip; to the other half one or more drops of the saturated methylene-blue solution are added, enough to stain a paper slip distinctly blue. A drawback in the use of these solutions is the precipitation of crystals which form a scum on the surface of the solution. This scum is easily removed by slightly passing the smoothly cut edge of a piece of filtering paper over it. The crystals are thus moved to the periphery or cling to the filtering paper, and the surface of the solution becomes absolutely clear.

Cover-glass preparations of blood must be in readiness. These preparations are made after the Koch-Ehrlich method. A drop of blood is spread on a cover-glass in the usual manner, forming a very thin layer, so that the individual blood-corpuscles are separated from each other.[1] The cover-glass preparations are heated for about two hours at a temperature of from 120° to 125° C., preferably in a copper heating apparatus. After this the preparation is floated for about three minutes on the solution containing eosin in excess; next it is similarly treated with the solution having the excess of methylene-blue. Having been dried the preparation is imbedded in damar or balsam in the usual manner. Specimens thus treated show the following peculiarities in normal blood:

All the erythrocytes assume a reddish-brown (maroon) tint, which is more or less sharply divided from the colorless central area (depression).

The intensity of the stain varies in different specimens derived from different individuals, between a light reddish-brown and a deep chestnut-brown, almost a black-brown. Different states of the blood show different color-reactions of the erythrocytes. The variation in the same individual on different days is sometimes very striking. Still more striking is the difference in the color of the blood of different individuals.

The blood-platelets (Bizzozero's corpuscles), too, are plainly stained by this method. In another publication (*Centralblatt für die medicinischer Wissenschaften*, 1894, No. 20), I have shown these, the so-called third corpuscular elements of the blood, to be nothing else than the products of physiologic decay of the erythrocytes. Often they can be seen in the act of expulsion from the erythrocyte, only parts of them protruding. Their color varies between a decided rich, deep blue and a violet. They are always more or less basophilous, showing affinity for the methylene-blue

The nuclei of the leukocytes are stained pure blue; the intra-nuclear network shows often very plainly. All epsilon-granulations (Ehrlich's) present themselves in a violet stain. The granulations of the alpha-cells are of a bright-red color. Slightly basophilous (methylenophilous) are the nuclei of the medium-sized lymphocytes, the protoplasm of which is generally stained blue, and contains basophilous (blue) granulations. Finally, the smallest lymphocytes have intensely blue nuclei and only a slightly blue protoplasmic margin.

The great advantage of this method consists in this, that the blood-plasma, too, assumes distinct and definite hues, according to its chemic constitution. Generally its reaction is slightly neutrophilous; often, however, it is of a deep reddish-brown stain, due, no doubt, to the exudation of the hemoglobin from the erythrocytes. This exudation or effusion is the result of the drying and shrinking of the protoplasm of the red blood-corpuscle or diskoplasma.

Among the many changes alluded to, about the nature of which I am still in the dark, that observed in diabetes is most characteristic and striking. It consists in the complete loss of the eosinophilia of the erythrocytes. This loss is demonstrable in the blood of all persons in whose urine sugar can be shown to occur by the ordinary clinical tests.

In all instances that have come under my observation so far, comprising cases of typical diabetes, as well as glycosuria of a more or less transitory character, the staining peculiarity just mentioned could be shown to exist. So exact and certain is this reaction that on various occasions, in fact, in a majority of the cases examined, I was enabled to predict sugar in the urine, even in persons in whom not the slightest suspicion of glycosuria existed.

---

[1] A far superior method of spreading blood for the purposes of histologic and pathologic study I shall publish shortly in another place.

In such preparations the erythrocytes either remain entirely unstained, or they are of a slightly yellow or greenish-yellow tinge. Rarely there is a narrow peripheral zone of the erythrocyte stained red (eosinophilous). The plasma, too, remains colorless, or is at most slightly rose-colored, a proof that it is not the loss by effusion of the hemoglobin that causes the lack of coloration of the erythrocytes, but that a chemic change has taken place in the diskoplasm.

Together with this anomaly of color-reaction in the erythrocytes there are certain changes in the granulations of the lymphocytes and in the products of disintegration of the erythrocytes, *i. e.*, the blood-platelets. A description of these changes (in the platelets) I shall reserve for another publication.

Again, in all of the cases of diabetes and glycosuria examined by me up to the present time another peculiarity is demonstrable quite characteristic (at any rate so far as the quantity is concerned) of diabetic and glycosuric blood. It consists in a superabundance of white and generally globular bodies of varying sizes. They seem to be of the same chemic nature and morphologic appearance as the minute unstainable granules that are found in the blood of healthy individuals, and which by some have been called elementary granules. None of the known coloring agents will stain them. As to their nature and origin, they are necrotic substances derived from decaying erythrocytes (their products of decay being the platelets), leukocytes, and lymphocytes. The amount and the individual size of the granules are so large in some specimens of diabetic blood that the plasma appears more or less coarsely granulated. They are plainly enough demonstrable by the staining method described, but the pictures obtained by the Gram method are much more striking. In some cases these necrotic masses seem to preponderate over the plasma, a fact that possibly explains, or, at all events, renders intelligible the nervous and general symptoms of diabetes and glycosuria. Another peculiarity quite characteristic of the kind of blood in question is a very clear, sharply-defined, narrow, white zone surrounding the nuclei of the white-blood corpuscle (leukocytes and lymphocytes and alpha-cells). They often describe all sorts of curves around the nuclei; a frequently recurring curve is the C form. I take these white contours to be indications of limited necrosis of the protoplasm of respective cells. Only in two out of fifteen cases were these peculiarities not demonstrable.

Whether this abundance of necrotic globules is in connection with the color-reaction described, or whether there exists another characteristic constituent of the sugar-blood causing the reaction, has to be determined by future experiments. Against the former assumption speaks the fact that the blood in certain cases of nervous cachexia is loaded with white globular masses of apparently the same nature with those just treated of, and yet the tinction of the erythrocytes is the normal one.

It is somewhat strange that the erythrocytes of sugar-blood are refractory in their elective affinity only to eosin, whilst other acid anilin dyes (scarlet, aurantia, and acid fuchsin) stain them easily.

One might be led to assume that the abnormal amount of sugar in the blood is responsible for the loss of the eosinophilous reaction of the erythrocytes. But a simple experiment refutes such an assumption. If a cover-glass preparation of normal (non-diabetic or non-glycosuric) blood be treated with a solution of grape-sugar, the color-reaction is the normal one. If, however, a cover-glass preparation smeared with non-diabetic or non-glycosuric blood, heated in the usual way, be floated for a short time, say twenty-five or thirty minutes on diabetic or glycosuric urine, and then be stained by the eosin-methylene method, the typical reaction sets in; the erythrocytes lose their eosinophilia. They appear slightly greenish-yellow. The counter-experiment, treatment with non-diabetic urine, is negative. Neither does urine, to which grape-sugar has been added, change the normal stain. I have not succeeded as yet in diagnosticating the greater or lesser amount of sugar in the urine from the various degrees of loss of eosinophilia in the erythrocytes. Nor is it possible to diagnosticate simple or transitory glycosuria from genuine diabetes by this staining method. There seems to be, however, no doubt that the loss of the eosinophilia bears a certain proportion to the percentage of the sugar. Likewise, the white granular masses are generally proportionate, both in size and amount, to the gravity of the case. They are likely to remain in cases of glycosuria, when sugar is no longer demonstrable in the urine. Such cases are, in my opinion, in danger of relapse. Finally, there are cases in which the reaction is somewhat dubious, and in which only a suspicion is raised by the appearance of the blood, *i. e.*, the stain is nearly, but not quite, the typical sugar-stain.

In glycosuria artificially produced by phloroglucin, for instance, with a daily dose of 0.6 administered during three consecutive days, the mentioned reaction of the erythrocytes could likewise be demonstrated. The presence in abundance of the white granular masses could be established.

Gabriczewski[1] has claimed that glycogen can be demonstrated in the leukocytes of diabetics. I have not been able to verify this observation.

The material of my investigations is confined at present to fifteen cases. Of these, six are genuine cases of diabetes; six are patients in whom nervous troubles, generally of a neurasthenic character, exist (one of them traumatic neurasthenia); two present nervous symptoms dependent on luetic infection; one has struma, but presents no subjective symptoms. In the great majority of these cases the presence of sugar in the urine was foretold by the behavior of the erythrocytes toward the eosin methylene-blue staining method, and the presence of the white granular masses as shown by the Gram method.

HEMORRHAGE FROM THE UMBILICAL CORD ON THE TENTH DAY.

BY A. RHETT STUART, A.M., M.D.,
OF WASHINGTON, D. C.

In The Medical News of November 17, 1894, was an article on "Umbilical Hemorrhage, not Due to Loose Ligature or from Laceration of the Cord, but Due to a Hemorrhagic Diathesis, Weakened and Diseased Vessel-walls, or an Inherited Taint of the Blood." That such cases are of rare occurrence I cannot agree. I am of the opinion that they occur frequently, but that they are often not recorded, but regarded by the attending physician as nothing very rare or remarkable. The only thing that attracts his notice, to his sorrow and disappointment, is that, notwithstanding all devices and ways and means of treatment, both surgical and medical, he fails to control the hemorrhage, and death is the inevitable result. I consider that this hemorrhage from the cord, which is always so fatal, occurs usually only in those infants that are born of scrofulous or syphilitic parents, and in whom the tainted, impure blood is inherited; the diseased and weakened vessel-walls also are inherited; in truth, all the organs of the body do not escape the impurity.

---

[1] Arch. f. exp. Path., Bd. 28, p. 272.

A short time ago I was called to see a patient, a baby ten days old, apparently in good condition. On inquiring what was the matter the mother informed me that the baby's cord had been bleeding for two hours, and on lifting the outside dress I found that quite a hemorrhage had taken place, the undergarments being saturated with blood. The mother told me that the cord had fallen off five or six days before, and everything was progressing nicely until she noticed the blood, which had soaked through the clothes. I at once quickly exposed the cord to view, and noticed the blood oozing and welling up drop by drop and trickling down over the belly from the apparently non-ulcerated but healthy-looking stump of the desiccated cord. It reminded one of the water bubbling through the sand at the bottom of a spring, only the oozing and welling up from the stump of the cord were very deliberate and slow.

The infant was placed on a pillow upon a table, and Monsel's solution applied in and around the stump with apparent success, for after using it the blood ceased flowing, and after waiting fifteen minutes and seeing no signs of continued hemorrhage, I placed over the stump a large compress of absorbent cotton and a closely-applied bandage, and left.

In three hours' time I was summoned again to find a renewal of the bleeding, which must have started a few moments after I left the house, for the compress and bandage were both completely and thoroughly saturated with blood, although a large amount of cotton was used as a compress. I exposed the stump again after administering three drops of brandy in a teaspoonful of water, and found the blood oozing slowly up, drop by drop, as before. I sent out for a stick of silver nitrate, which I applied sedulously, but only with the effect of stopping the oozing for a few moments..

Tannic acid, powdered, with powdered iron subsulphate, was next used, making an inky-black paste with the liquid blood, on account of their incompatibility; but by pasting the stump up in this manner the blood ceased to flow for one hour, and I was about to leave, when on close examination one little drop of blood was seen to well up afresh. I then sent out for a solution of plaster-of-Paris, which Vogel speaks of as having been used with success, but I could not get it, either because it was so early in the morning the druggists did not wish to be disturbed, or because there was none in stock.

Having then determined to ligate the stump immediately, I sterilized two large sewing or knitting needles about three inches long, and transfixed the stump close to the abdominal wall, the needles being at right angles, and by pulling it up ligated tightly the stump both below and above the transfixing needles, in two places, with two separate pieces of thread.

After taking the needles out I applied the medicinal treatment that had acted best before, that is, the powdered mixture of tannic acid and iron subsulphate, making a mound of this mixture around the stump, using it freely and abundantly. Having waited a little while, and again seeing no evidence of continued hemorrhage, I placed on a compress and bandage, and left the house for a little rest and sleep, feeling more confident and hopeful of my treatment being successful, and thinking that by no possible means could any more blood escape. I told the parents that if they noticed any blood on the bandage to send for me, and that as a last resort I would cut down and find the bleeding points and apply ligatures directly to them; and if that failed, I could do nothing more. Not being sent for, I called the next morning at 11.30 o'clock, but little hopeful of successful news, and therefore was not surprised to find that the baby had died at 7 A.M., though no blood had appeared on the outside of the bandage. Wishing to see if there had been much hemorrhage following the strong double ligatures of the stump, I exposed it and found that there had been considerable oozing on all the compresses except the top layer. I would say here that the compress was not so thick or abundant as before, for I considered that the baby had but little more blood to lose without death as a result, and I wished the slightest oozing to be seen by soaking through the slight amount of cotton. The infant, of course, died from asthenia from the loss of blood from a hemorrhage that I could not control.

I doubt if cutting down surgically and finding and ligating the bleeding-points would have succeeded, for the little ones will bleed to death from the freshly-made incisions, and the vessels are not to be found to ligate, the blood oozing in every direction from the smallest capillaries between the layers of the skin and from the tissues. These children some would certainly claim to be, of course, born of hemophilic parents. But I repeat that these hemorrhages from the cord are very liable to occur in infants born of scrofulous or syphilitic parents, and resist just as obstinately the attempts to control and the ways and means of treatment, both surgical and medical, as a child born of hemophilic parents, thus inheriting a hemorrhagic diathesis.

A remarkable feature of this case was the location of the collateral hemorrhage, in the eyes, from the conjunctival mucous membrane, when the bleeding seemed to be controlled for a time at the umbilicus.

The mother of this child was markedly scrofulous, and no doubt syphilitic. Indeed, five days after the baby's death I was called to see the mother, who lay in collapse with bloodless white tongue and mucous membranes, caused by the loss of blood from a profuse hemorrhage of the uterus on the fifteenth day after labor. This hemorrhage was controlled with difficulty by 20-minim doses of an active preparation of ergot by the mouth every two hours for twenty-four hours and thereafter for a few days, gradually reducing the amount of dosage until 3 minims every two hours were given during the day for several days. The uterus was immediately packed, as well as the vagina, with iodoform-gauze in the usual manner, the packing remaining in place twenty-four hours, and on removal, after a cleansing antiseptic douche of the uterus and vagina, the yellowish lochial discharge made its appearance naturally and without odor.

The woman was brought out of the collapsed state she was found in by persistent stimulation from the beginning, using heat externally, and whisky, digitalis, and strychnin internally—coffee and liquids being used in large amounts on regaining consciousness, to increase the volume of the blood in the almost emptied vessels.

7 DUPONT CIRCLE.

A CASE OF ECLAMPSIA, WITH THE EXHIBITION OF VERATRUM VIRIDE.

BY A. M. DAVIS, M.D.,
OF GERMANTOWN, PA.

L. M., twenty-five years of age, a primipara, with a negative family history, had previously always enjoyed good health. When first seen the patient gave a history of having been pregnant six-and-one-half months. Physical examination revealed an individual of good physique, but poorly nourished, the mucous membrane of the lips and conjunctivæ being markedly anemic and the general complexion sallow. The heart-sounds were apparently normal, the first sound being perhaps slightly accentuated. The abdominal parietes were moderately distended, palpation revealing an L. O. A. position, with the fetal heart-sounds heard distinctly below and to the left of the umbilicus. The lower extremities were moderately edematous, this symptom having appeared for the first time one month previously. Examination of the urine showed it to be acid in reaction, with a specific gravity of 1010, and to contain about 30 per cent. of albumin by bulk, with a few hyaline and pale granular casts, the quantity secreted in twenty-four hours being slightly below normal. About this time colliquative diarrhea developed, which failed to respond to ordinary remedies.

The patient was made to rest in bed during part of the day, being restricted to a skim-milk diet and given the solution of iron and ammonium acetate (Basham's mixture), which had the effect of increasing the quantity of urine to three quarts or more during twenty-four hours. Urinalysis revealed a relatively less quantity of albumin. Notwithstanding this apparent improvement in the urinary symptoms the edema extended over the entire surface of the body (the stethoscope when used to auscultate the precordia leaving a pressure ring), and black spots before the eyes, with failing vision, began to appear, so that one week after the physician's attention had been first directed to the case the induction of premature labor was gravely considered. At this time, without apparent cause, signs of beginning labor began to manifest themselves, and twenty-four hours later delivery took place, labor being entirely normal, and the product of conception, apparently healthy, weighing 3½ pounds.

Within thirty-six hours after the birth of the child, lactation was established, the anasarca, diarrhea, and amblyopia, however, still continuing. The quantity of urine excreted varied from three to four quarts during the twenty-four hours, and the secretion still contained 30 per cent. albumin by bulk, and was of low specific gravity. The pulse became rather rapid and of high tension, although not full and bounding. The pupils were somewhat dilated and responded feebly to light. Forty-eight hours after delivery the patient, without warning, was seized with a convulsion, beginning in the muscles of the face and involving those of the trunk and upper extremities, accompanied by complete unconsciousness. The attack lasted about three minutes, at the end of which time consciousness was partly recovered, the patient being in a semi-stuporous condition and unable, to a certain extent, to control the movements of the facial muscles. During the attack, inhalations of chloroform were promptly administered (which lessened the intensity of the spasm), and an enema of croton-oil (three minims) in glycerin was given, and proved effective. This was followed by one of chloral hydrate and potassium bromid, the latter enema being repeated in three hours. Diaphoresis was freely produced by alcoholic vapor obtained by wrapping saturated cloths about hot bricks.

Two other convulsive seizures followed at intervals of about an hour (both typically like those of eclampsia) the last occurring with greater severity and extending over a longer period of time than the two previous ones. The patient recovered consciousness slowly, the temperature registering 102° F., the pulse being 136 per minute, and of high tension but of moderate volume. The heart-sounds were distinct and forcible, the muscular element of the first sound being accentuated. The pupils were widely dilated, and the skin was warm and moist. Two hours after the cessation of the eclamptic attacks, as the character of the heart-sounds, the frequency of the pulse, and the increased blood-pressure had not changed perceptibly, five minims of the fluid extract of veratrum viride were given hypodermically under antiseptic precautions. As no apparent effect was produced by this administration, in one-half hour another injection containing the same quantity of the drug was given, which had the effect of reducing the pulse-rate from 136 to 108 beats per minute, and of causing a decided diminution in the degree of arterial tension.

Three hours after the occurrence of the final convulsive seizure the patient began to exhibit marked restlessness, which was controlled perfectly by morphin sulphate (gr. ¼) and atropin sulphate (gr. $\frac{1}{150}$), the patient falling into a quiet sleep. On account of the existence of chronic nephritis, morphin was not used primarily, nor persisted in.

In twenty-four hours from the onset of the attack the temperature had fallen to normal and the pulse-rate numbered 86 beats per minute, the bounding quality of the pulse having largely disappeared; vision was apparently normal, and the patient's mental condition much improved.

The urine excreted during the twenty-four hours following the attack measured two quarts, containing fully 30 per cent. of albumin by bulk, with hyaline and pale granular casts. The patient was restricted to a skim-milk diet and urged to drink large quantities of mineral water. Medicinally diuretics were administered, and bags containing heated salt were placed under the loins to stimulate the kidneys to increased secretion. In three days following the attack, the edema had entirely disappeared; the quantity of urine excreted measured three pints in twenty-four hours, the secretion still containing, however, about the same proportion of albumin, with the presence of casts. The milk-secretion (which was well established within thirty-six hours following delivery) rapidly lessened after the convulsions, and had almost entirely disappeared one week later. Improvement in the general symptoms was uninterrupted, the patient recovering sufficiently to leave her room five weeks after delivery. At this time the quantity of urine voided daily varied from two to three pints, and analysis revealed as follows: sediment abundant and flocculent, reaction acid, specific gravity 1013; mucus, a moderate amount; albumin, 20 per cent. by bulk; urea, a trace (0.77 per cent.). Microscopically, renal epithelium with a few pale and dark granular casts were seen.

The child, whose nails had not nearly reached the finger-tips, and on whose body lanugo was scarcely perceptible at birth, took nourishment from the bottle well, and is apparently healthy.

THE VALUE OF THE ANTITOXIN-TREATMENT ILLUSTRATED BY TWO CASES OF DIPHTHERIA.

BY L. WOLFF, M.D.,
CLINICAL PROFESSOR OF MEDICINE, WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA; PHYSICIAN TO THE GERMAN HOSPITAL, PHILADELPHIA, ETC.

ON January 12, 1895, I was called to see two of the children of A. S. They were respectively a boy of seven years and a girl of two years and eight months. They had both been previously in good health, although I had treated the boy for scarlatina some years ago. On examination I found the boy had tonsillar diphtheria, and in the girl the diphtheric deposits could be seen on both tonsils, the arches of the fauces, and the uvula.

With an improvised sterilized mop I detached some of the deposit from each of the two and inoculated two culture-tubes that had been prepared at the Bacteriological Laboratory of the German Hospital. Microscopic examination, in twenty-four hours, of the stained culture showed Klebs-Loeffler bacilli in great profusion.

The boy, who was able to do so, was ordered to gargle with a diluted solution of liquor sodæ chloratæ 1 : 60, alternately with a spray of hydrogen dioxid, every hour, together with calomel internally, 3 centigrams, every three hours. Milk and whisky were also ordered.

The girl, who could not gargle, was treated locally with the hydrogen dioxid spray alone and centigram-doses of calomel. Through the courtesy of the German Hospital authorities I was able to procure one bottle of Behring's antitoxin No. 1, which had been personally brought to this country by Mr. Charles Meyer, Imperial German Consul in this city. This was injected in one dose into the little girl, and the calomel-treatment was stopped. The same day laryngeal stenosis developed in her case, and with the aid of my friend Dr. Rosenthal intubation was performed. The visible deposits in the throat seemed to have diminished the following day, and had entirely disappeared three days subsequently. The tube was removed after forty-eight hours, and the little child made an uninterrupted recovery.

The boy's case seemed to have progressed favorably for the first two or three days, when reinfection occurred, and spreading of the deposit all over the arches and uvula was noticed. Not being able to obtain any more antitoxin at the time, the original treatment in his case was adhered to, stimulants were vigorously pushed and strychnin was added, but in spite of our efforts the child died from general toxemia on the tenth day.

I publish these cases as an illustration of the value of the antitoxin. The younger child was the more seriously affected from the start, and recovered. It might readily be inferred that the older and stronger of the two, with a milder infection, would have survived could the antitoxin have been used in his case also.[1]

MEDICAL PROGRESS.

Diphtheric Vulvitis in a Child.—GNICHTEL (*Journal of Cutaneous and Genito-urinary Diseases*, No. 147, p. 532) has reported the case of a girl, one year old, who for five days had been irritable and restless and appeared to suffer pain referred to the genital region, the symptoms being aggravated during micturition. Examination disclosed several patches of false membrane covering anteriorly the internal portion of both labia majora and nymphæ and invading the urethral orifice. The membrane was firmly attached and grayish-white in color. It was further learned that two fatal cases of diphtheria had recently occurred in the house in which the child resided, the last but a week before she was taken ill. There were no other symptoms. Bacteriologic examination of the membrane revealed the presence of diphtheria-bacilli. The patches disappeared upon the use of local applications, chiefly of hydrogen dioxid and mercuric chlorid, and the child made a good recovery. At no time were marked constitutional symptoms observed.

Nephrectomy for the Relief of Congenital Hydronephrosis in an Infant Two Years Old.—At a recent meeting of the Société de Chirurgie MARTIN (*Revue de Chirurgie*, 1894, No. 12, p. 1074) reported the case of a child, two years old, presenting a cystic tumor occupying almost the entire abdominal cavity, and having progressively developed from the time of birth. Puncture gave exit to twenty ounces of fluid having the odor of urine, and was followed by paroxysms of intense abdominal pain attended with vomiting. Subsequently, lumbar nephrectomy was successfully performed. Examination showed that the morbid condition was due to congenital narrowing of the ureteral orifice.

Pseudo hypertrophic Paralysis in an Old Person.—DESTARAC (*La Médecine Moderne*, 1894, No. 89, p. 1387) has reported a case of pseudo-hypertrophic paralysis in a man, sixty-eight years old, without hereditary predisposition. The mode of onset, the course of the disease, and the absence of reaction of degeneration excluded the possibility of error. Without creating a senile type of the disease in contra-distinction to the congenital type, it is pointed out that pseudo-hypertrophic paralysis may occur at all ages and in its various forms in the same family.

---

[1] No post-diphtheric paralysis has shown itself in the girl at the date of writing.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

SECRET MEDICINES AND THE TEMPERANCE-REFORM LEAGUE.

EDWARD EVERETT HALE in a magazine article thus writes of "Secret Medicines:"

"The audacity with which the so-called cures of intemperance are advertised is attracting general attention, as well it may. The matter is too important for good-natured neglect. Careful analyses have been made of medicines used in some of the much-advertised institutions, with very damaging results.

"There must be no secrets where life is concerned. The medical profession is a liberal profession, and not a trade, because it has always adopted this principle. What is paid to a physician is his *honorarium*. It is paid to him in recognition of his services to mankind, not simply as a purchase of his advice in the case in hand. Because this is so—because, indeed, life is something which cannot be balanced against dollars and cents—no physician who cares for his reputation keeps secret a method which he believes is useful to mankind. He makes it public, as PAUL made public the gospel when he landed on the coast of Europe. All medical associations of any character recognize this fundamental necessity. And the moment when any physician refuses to be bound by such a rule, that moment, of his own accord, he cuts himself off from a liberal profession and makes himself what is properly called a quack."

He then quotes MISS WILLARD on the gold-cures and on that meaner class of hypocrites who gain credit among reputable physicians by falsely pretending that they have a "Sanitarium for Nervous Diseases," or institutes in which "*no secret remedies are used.*" A fraud of this species was discovered by the Temperance-Reform League in Boston lately, who evades making public his gospel, and who stands high among the Prohibitionists. Says MISS WILLARD:

"White Ribboners do not believe that he has this right, or that the men who establish 'cures' throughout the country, and coin money out of them, have the moral right to do so. We believe that the English view is the true one: that any physician who has made a discovery, or who claims to have made one, which will alleviate the suffering of humanity, wrongs his fellowman and his profession if he does not make that discovery public."

"The following passages," continues DR. HALE, "are from an interview with GEORGE F. ORMSBY, published in the Boston *Herald:* 'Physicians whose eminence in their profession is generally conceded by the people of this country have disagreed with the venders of secret medicines for inebriates. Material medicines have only to do with material bodies; inasmuch as the weak will, the bent of mind, is something peculiar to the soul—something which the soul carries with it after the body becomes dust, the doings of the quack are as idle as to hope to bring salvation to a ghost by injecting hypodermic syringes into its grave. Purgatory is not thus to be escaped. Where a depravity of taste is produced and maintained by alcoholic disturbances of bodily functions, there drugs are efficacious. But drugs cannot cure a man of his memory. And his memory reminds him that rum once tasted very good. When his physical health has become perfect, when the ravages of brandy have been wholly repaired, only his memory, his habits, and his disposition to pleasure—spiritual things all of them—are his foes. How can these spiritual enemies be annihilated except through spirit conquerors!'"

MR. ORMSBY, who is attorney for the Temperance-Reform League, urgently invites any and every physician who is not using a secret remedy, and who knows of any formula that will antidote the drink-crave proper, to publish it in THE MEDICAL NEWS.

The Temperance-Reform League is an organization for the reformation of drunkards and those addicted to drug-habits, and to prevent drunkenness and intemperance by all proper, honorable, and non-secret methods. The league has employed expert chemists to analyze the secret so called cures, and finds that many of the "cures" or "tonics" of the alcoholic habit "contain from 7 to 35 per cent. of alcohol," and that 20 samples of the "opium-cures" contain morphine. MR. ORMSBY's address is 113 Devonshire Street, Boston.

MYASTHENIA GRAVIS PSEUDO-PARALYTICA.

UNDER the designation *myasthenia gravis pseudo-paralytica* JOLLY (*Berliner klinische Wochenschrift*, 1895, No. 1, p. 1) describes a peculiar condition in which fatigue of the voluntary muscles is readily induced by exercise. He reports at length one typical case and cites another previously reported, both occurring in boys about fifteen years old. A search through the literature has resulted in the discovery of but fifteen other cases that belong to the same clinical category, one of JOLLY's and ten of these terminating fatally. In some of the remainder recovery or distinct improvement ensued, while in others the outcome was not known.

In the first cases reported the symptoms were believed to be of bulbar origin, and the same conception of the pathology was adopted by subsequent observers. At most of the autopsies, however, no morbid changes in the nervous system were found, and the involvement in some cases of the extremities, as well as of the muscles supplied by the bulbar nerves, tended to show that the lesion was not always restricted to the higher nervous centers. In one case in particular degenerative changes were found throughout the entire length of the cerebrospinal nervous system, from the ocular nuclei to the sacral cord. It might be conceived that various degrees of alteration took place in different cases, from the slightest to the most profound; but there seems reason to believe that the cases thus grouped together are really of several different kinds. One is thus forced to the conclusion that while in some structural changes are present, there are others in which such changes are not demonstrable.

As intimated, the characteristic phenomenon is undue readiness of fatigue of voluntary muscles after ordinary functional activity. The function of the affected muscles is not lost, but movements at first well performed are gradually effected with greater and greater difficulty, until finally they become impossible. The disturbance is less pronounced after rest, and particularly in the morning after sleep.

The motor derangement is not restricted to any group of muscles, but often involves those supplied by the bulbar nerves, and in some instances also those of the extremities. Nutritive changes do not occur. Spinal curvature may result from involvement of the vertebral muscles. Intermissions, sometimes attended with improvement, may occur in the course of the disease, but death is likely to ensue from the dangers attendant upon the dysphagia and the interference with respiration.

The reflexes, as well as sensibility, are preserved. The muscles respond normally to faradic currents of ordinary intensity, but to tetanizing currents they behave as they do to volitional impulses—that is, the tonic contraction, at first readily induced, grows gradually feebler and feebler until it finally ceases altogether. Degenerative reactions do not appear. For this peculiar electric reaction the designation myasthenic has been proposed. It corresponds in some respects with the reaction of exhaustion.

In diagnosis the differentiation from pseudo-hypertrophic paralysis and progressive muscular atrophy may be necessary; but, as already stated, there is neither enlargement nor wasting. The condition appears to be the antithesis of THOMSEN's disease, or congenital myotonia, in which there is difficulty in movement after a period of rest, gradually subsiding with the persistence of the volitional impulse. In both conditions it is by some believed that there is an abnormal state of the muscles dependent upon changes in the ordinary metabolism. It has also been shown that similar muscular conditions can be developed temporarily by the administration of certain drugs. Thus veratrin, physostigmin, and digitoxin are capable of inducing the muscular phenomena of myotonia and protoveratrin (a body allied to veratrin) those of myasthenia.

Therapeutically the most important indication is rest, and both exercise and electric stimulation are to be sedulously avoided. Particular attention is to be directed to the general nutrition, which should be maintained at the highest level possible.

EDITORIAL COMMENTS.

The Suppression of the Nostrum Traffic.—In contrast with the efforts on the part of some members of the American Medical Association, as representative of the medical profession, to exorcise certain salutary restrictions from the Code of Ethics are the numerous indications of a disposition on the part of the dental profession to elevate its standard both ethically and educationally. While certain men in the medical profession look upon nostrums with indifference, if not with encouragement, the dentists are discussing measures for the suppression of unethical practices of all kinds.

In a paper read some time ago before the First District Dental Society of the State of New York, Dr. E. C. Kirk, of Philadelphia, showed that a large number of nostrums recommended for the relief of various painful affections of the teeth and gums contained cocain, despite the emphatic assertion to the contrary in most instances. The danger of the indiscriminate use of such preparations in unskilled hands is entirely too obvious to require extended comment, and calls for restrictive legislation of some sort. The *Dental Cosmos* in its February number notes editorially that a movement has been set on foot in Mississippi having for its object the prohibition by legislative enactment of the use of nostrums in connection with the extraction or filling of teeth. The agitation is a timely one, and should find the most cordial indorsement and support wherever intelligence and honesty prevail over ignorance and quackery. The restrictions in the use of dangerous remedies or such as are not what they are pretended to be, should, however, not be limited to any one class or variety, but should be extended to include all preparations the nature of whose composition is concealed. Dentists and physicians might well join hands in support of such salutary legislation and institute measures looking to its enactment and enforcement.

Loeffler's Toluol Solution.—Numerous inquiries have been directed both to Dr. E. J. Kuh and to THE NEWS concerning the constitution of the solution of toluol referred to in the article that appeared in THE NEWS of January 26, 1895, p. 100. It was really an omission that the formula was not given at the time, and we are glad to take this opportunity to make the deficiency good.

The solution is made by taking of menthol 10 grams (ʒijss), and adding sufficient toluol to make 36 c.c. (fʒx), and finally adding 60 c.c. (f℥ij) of alcohol and 4 c.c. (fʒj) of solution of ferric chlorid. The affected parts are first cleansed with a cotton swab held in the grasp of forceps, and then the application is made thoroughly by means of a fresh swab saturated with the solution. Precautions are to be taken by means of a face shield or other protection against infection from coughing, which is likely to occur as a result of the application. This should be practised at intervals of not less than four hours.

As Loeffler points out, this mode of treatment in nowise antagonizes or is counter-indicated by the employment of injections of the antitoxin. It has the further advantage of being serviceable in doubtful or suspicious cases and in the treatment of the various non-diphtheric anginas.

The prescription is spoken of in terms of warmest praise by those who have used it, and is deserving of further trial. One enthusiast is quoted as saying that he would prefer the combination to the antitoxin.

Angio-paralytic, or "Pulsating," Neurasthenia is the designation given by DANA (*Journal of the American Medical Association*, vol. xxiv, No. 4, p. 110) to a condition observed in neurasthenic patients, characterized by a sense of beating, of which they never lose consciousness. The tension of the pulse is low and the rhythm normal or but slightly accelerated. Palpitation is, as a rule, not present. There may or may not be tremor, but dermographism and epigastric pulsation are commonly present. Pressure on the carotid stops the beating. There are usually insomnia, nervousness, and mental depression. The condition has been observed in young men and in adults under forty. The abuse of tobacco and alcohol is sometimes an exciting cause. There is believed to be an abnormal relaxation of the arterioles and capillaries, so that the blood is thrown into vessels that have lost their resiliency and the pulse-waves are not fused together. The condition appears to correspond closely with that described by S. SOLIS-COHEN (*American Journal of the Medical Sciences*, February, 1894, p. 130) as vasomotor ataxia, of which it may be considered a sub-variety. In the milder and less typical forms cure is effected by the use of general and vasomotor tonics. In the more advanced cases ligation of an artery has yielded the best results. A prescription containing ferric chlorid, gr. ¼, potassium bromid, gr. x, hydrobromic acid, ♏ viij, and spartein sulphate, gr. iij, affords relief in many cases. Monobromated camphor and strychnin are often useful. Hydrotherapy is also to be recommended.

The Philadelphia Polyclinic is to be complimented both upon its improved appearance and upon the improved character of its general "make-up." Its editorial direction has fallen into strong and trustworthy hands, and the publication promises to exercise an important and salutary influence on ethical medicine and ethical journalism. The *Polyclinic* has further ranged itself with THE NEWS among the few weekly medical journals that acknowledge the pecuniary value of the literary work of medical men by making payment in cash or reprints for contributions.

SELECTION.

THE PRESIDENT OF HARVARD COLLEGE ON FOOT-BALL.

THE evils of the intercollegiate sports, as described in the president's report of last year, continue without real redress or diminution. In particular, the game of foot-ball grows worse and worse as regards foul and violent play and the number and gravity of the injuries the players suffer. It has become perfectly clear that the game as now played is unfit for college use. The rules of the game are at present such as to cause inevitably a large number of broken bones, sprains, and wrenches, even during trial or practice games played legitimately;

and they also permit those who play with reckless violence or with shrewd violations of the rules to gain thereby great advantages. What is called the development of the game has steadily increased its risks, until they have become unjustifiable. Naturally the public is losing faith in the sincerity of the professed desire of coaches, captains, and promoters to reform it.

It should be distinctly understood, however, that the players themselves have little real responsibility for the evils of the game. They are swayed by a tyrannical public opinion—partly ignorant and partly barbarous—to the formation of which graduates and undergraduates, fathers, mothers, and sisters, leaders of society, and the veriest gamblers and rowdies all contribute. This state of mind of the spectators at a hard-fought foot-ball match at Springfield, New York, or Philadelphia cannot but suggest the query how far these assemblages differ at heart from the throngs which enjoy the prize-fight, cock-fight, or bull-fight, or which in other centuries delighted in the sports of the Roman arena. Several fatal accidents have happened this year to schoolboys and college students on the foot-ball field; and in every strenuous game now played, whether for practice or in an intercollegiate or other competition, there is the ever-present liability to death on the field.

It is often said that by employing more men to watch the players, with authority to punish instantly infractions of the rules, foul and vicious playing could be stopped. The sufficient answer to this suggestion is that a game which needs to be so watched is not fit for genuine sportsmen. Moreover, experience indicates that it would be hard to find trustworthy watchers. Extravagant expenditure for the teams throughout the season, and by the spectators at the principal games, continues to disgust the advocates of simple and rational manly sports.

Meanwhile it is to be observed that there is much wholesome physical exercise taken and much genuine athletic sport enjoyed in the university, in ways wholly independent of these exaggerated intercollegiate games. The variety of the exercises and sports is always increasing. For two years past the class exercises on the floor of the gymnasium have been very useful; and during the current year military drill has been introduced.

The athletic sports and exercises which commend themselves to sensible teachers and parents are those which can be used moderately and steadily, and which remain available in some measure in mature life. Such are gymnasium exercises, walking, running, rowing, sailing, riding, cycling, tennis, gunning, bowling, and fencing. The youthful expert in any of these sports and exercises will carry into his strenuous professional life a great source of enjoyment and a real safeguard of health and of the invaluable capacity to endure without injury mental and moral stress. On the other hand, the games which demand so much practice and such severe training that the brain is temporarily dulled for all other use, or which require a combination of many individuals of like powers and tastes, or which contain as essential elements violent personal encounters, can have no direct application in the after-life of professional or business men. Moreover, all games which require intense training for short periods present a serious physical and moral danger for the players, the familiar danger of reaction when training stops. In education, therefore, it is the moderate and long-available exercises and sports which alone have real interest and value. The intense, highly competitive sports afford some stimulus for other and better things, but this stimulus is now too dearly bought.—*From Annual Report of President Eliot.*

CORRESPONDENCE.

ENTERIC FEVER IN PREGNANCY.

To the Editor of THE MEDICAL NEWS,

SIR: I have just read in your issue of the 26th inst. the interesting "Case of Enteric Fever Occurring in Advanced Pregnancy," by Dr. Stryker, and am reminded of the record[1] I made on the same subject thirty-six years ago.

At that long-ago date, in writing up the history of one-hundred-and-thirty consecutive cases of enteric or typhoid fever, derived from private practice, I said:

"Pregnancy and lactation I have not found to have any material influence upon the character of the disease. In fourteen cases of intermediate gravity, pregnancy existed in five, the advance of which was two months in two, three months in one, four-and-a-half months in one, and six months in the remaining one. None of these miscarried.

"Among the cases of malignant type, pregnancy existed in one at an advance of two months. Miscarriage occurred on the tenth day of the disease, and was not followed by any serious result. The patient began to improve by the twenty-first day.

"Of those who gave suck, two were of the mild and one of the malignant type. In neither of the former was the child denied the breast. In the latter case, during the second week of the fever, the secretion of milk was entirely suspended; the child was removed to a neighboring family and not permitted its mother's breast for the next two months, when an abundant secretion again took place."

Concerning the use of veratrum viride, the same record goes on to say: "Besides its signal property as an arterial sedative, it is capable of producing other excellent effects, to some of which attention has not been much directed. I allude more particularly to its diaphoretic tendency, and that it possesses this to a marked degree, and experience with the remedy during the past two-and-a-half years in the management of this and other acute diseases enables me to speak of its action with no little degree of confidence. In all proper cases of enteric fever, according to my own experience, it is a safe, reliable, and valuable adjuvant to other means employed for its successful management. I have administered it to the young and to the aged, to the delicate and robust, in the pregnant state at all its periods, and have not had cause to regret its effect. The accusation that it is an abortic agent, and therefore its employment is unsafe in general practice, is, I am persuaded, wholly without just foundation. So far indeed from possessing a tendency to produce abortion, further experience may possibly establish that, in certain conditions, this medicine may be beneficially employed for the purpose of defending the pregnant state. If my own experience does not directly contribute to establish this fact, it at least assists in proving the remedy free from the charge preferred against it. The following case is given in point:

---

[1] Treatise on Enteric Fever. J. B. Lippincott & Co., 1859.

"Mrs. ———, thirty-six years of age, of very weak habit, the mother of seven children, aborted once at four months, sickened with enteric fever, January 1, 1858, pregnant at an advance of four-and-a-half months. During the first week the pulse ranged between 110 and 115 per minute, and by the twelfth day it was running at 130. Along with this state of the pulse there was restlessness, the skin hot and dry, pain in the small of the back and abdomen, with a slight show of blood from the vagina. Being warranted from previous experience to regard the veratrum viride as of service, I determined to bring my patient under its full influence. I began with Norwood's tincture, at the dose of five drops, and increased the quantity by two drops at each successive dose, every three hours, until the dose of eleven drops was reached, after which the pulse came down to 84, and the patient's condition was much improved, being free from pain, reduction of fever, and the whole surface covered with a gentle perspiration. To maintain this control of the symptoms, the dose of five drops was administered every four hours. Under the influence of this diminished dose the pulse ranged pretty steadily between 80 and 90 for the next several days. . . . The patient convalesced, went on to full term, and was delivered of a healthy child."

Away back in the forties and fifties the most successful plan of treatment of enteric fever consisted of diaphoretics, arterial sedatives, tepid and cold spongings of the general surface, to control excessive temperature. Now and then a heroic doctor could be found who resorted to cold wet-sheet-packs; the question as to the degree of fever being wholly decided by the feel of the patient's skin and condition of the pulse; for then the refinement of the clinical thermometer was not a vest-pocket ornament with country doctors. The sense of touch, cultivated to the most delicate impressions, was the guide, and the so-called "antipyretics" and "heart-failure" cut no figure in clinical reports. But now, in this year of our Lord, who can tell the number of patients that have been jeopardized by the readings of the clinical thermometer and the dread of innocent 103.5°!

Sincerely yours,

James E. Reeves.

Chattanooga, Tenn.

THE NECESSITY FOR A NATIONAL DEPARTMENT OF HEALTH.

To the Editor of The Medical News,

Sir: It is earnestly hoped that legislation for the establishing of a National Department of Health, or a National Health Bureau of some kind, will not be jeopardized or entirely defeated in the present Congress by differences among medical men as to the proper scope and character of the proposed law. The details of the scheme are of minor importance, and it would be well for medical men to waive somewhat in their preferences and endeavor to unite upon that which seems most feasible rather than divide upon different measures, and, from want of unanimity, secure nothing.

The importance of this measure can hardly be overestimated; nothing is of more importance than the health of the people, and there is every reason why there should be in the General Government a department or bureau charged with the duty of investigating the causes of disease, especially of epidemics, the collecting of statistics of diseases, health and mortality, and reporting upon all facts bearing upon the sanitary conditions of the people.

No one who has had occasion to examine the statistical reports of the health-boards in different cities and States of the Union need be told how imperfect, confusing, and unsatisfactory they are.

One of the first good results of the proposed department would be something like order and reliability in the reports from different parts of the country in the matter of disease and mortality, instead of the present incomplete conglomeration.

The President of the United States has, in his late message to Congress, recommended the inauguration of a National Board of Health, or similar national instrumentality, and a bill to that end is now before Congress. The scope of this bill is none too broad, nor its powers too great, for the work of collecting and collaborating reliable data as to the sanitary conditions in all parts of the country and presenting them in intelligible form as a basis for the action of local health authorities or of Congress.

Out of such a department we might expect to grow an institute similar to that founded at Berlin, under a special act of the German Government, for experimental investigations in the line of bacteriology.

A large part of the work of the antitoxin-treatment of diphtheria has been done in that institute or in connection with it. New discoveries in this direction are certain to be made, and we should have a national laboratory for such investigations.

The session of the present Congress ends in about four weeks from now, and if no action be taken before March 1st the question will go over to another Congress, and nothing may be done for two years or more.

Those who have this matter in charge should rouse themselves and push it at once and vigorously in some shape. If we cannot get the ideal measure, let us have what we can get.

Leonard Landes.

INFORMATION DESIRED AS TO THE EFFECT ON THE PROSTATE OF UNILATERAL CASTRATION.

To the Editor of The Medical News,

Sir: I would like to ask through your columns for information from surgeons in this country as to the effect of unilateral castration upon the total bulk of the prostate.

The existing evidence is scanty, but seems to point clearly to one-sided atrophy of the prostate as a common result of the removal of one testicle. Some experiments that I am now making on dogs corroborate this view, as does the observed condition of the prostate in monorchids. If it is found that the diminution in size extends to the other lobe, or if the shrinking of one lobe will in any large proportion of cases remove or lessen the mechanical obstruction to urination, it is obvious that the good effects of a simple and safe operation might at once be extended to a much larger number of patients and at an earlier and more favorable stage of the disease.

I now have several cases under observation, and hope by further experiment to throw more light on the subject; but conclusive clinical evidence must already be in existence, and I write in the hope that it will be sought for by those surgeons who have removed one testicle for disease or injury and whose patients are accessible for examination. I am, sir,

Yours, etc.,
J. William White.

1810 S. Rittenhouse Square, Philadelphia.

MORPHINISM IN CHILDREN.

To the Editor of The Medical News,

Sir: I am desirous of adding to the clinical literature of morphinism in children. If any reader of your journal has met with a case and will furnish me details, I shall appreciate the favor and give full credit.

Respectfully, J. B. Mattison.

Professor Ed. Külz, a well-known physiologist, died on January 13th, at Marburg, of appendicitis.

The Society for the Relief of Widows and Orphans of Medical Men of New Jersey was incorporated in 1882, and has continued to grow both in influence and membership. Since its organization 241 physicians of the State have become members, of which number 22 have died, 28 have been dropped for various reasons, leaving at the present time 191 active members. The Permanent Fund amounts to $1338.42, and it is intended eventually to allow small annuities to widows and minor children in cases of need. The amount already paid to the families of deceased members amounts to $2478. The total cost of conducting the society during the past year was $19.67.

A NEW DIAGNOSTIC SIGN FOR THE EARLY RECOGNITION OF CARCINOMA OF THE STOMACH.

BY D. D. STEWART, M.D.,
LECTURER ON MEDICINE IN THE JEFFERSON MEDICAL COLLEGE; DIRECTOR OF THE STETSON CLINICAL RESEARCH LABORATORY, ETC.

RECOGNIZING, through some experience in the management of gastric disorders by modern methods of research, the extreme value of data tending to the early diagnosis of malignant disease of the stomach and its separation from affections less grave that often intimately simulate it, it was with great gratification that I read the result of Boas' further investigations as to the significance of a lactic-acid reaction in gastric disease, first mentioned in the second edition of his work on the stomach. In the paper[1] in which the result of his research appears data were given so strongly supporting his earlier assertion, that a marked lactic-acid reaction indicates carcinoma of the stomach, that it was evident the matter merited the serious attention of the clinician.

The utter inability usually to diagnosticate positively a malignant gastric neoplasm in its early stage, when so situated that the presence of the tumor is undetermined until a period too late for surgical interference, naturally renders one who feels there is no higher court keenly desirous of more certain differentiation-methods than we possess. This is especially felt by the physician, also, on account of the anxiety he must experience in his frequent inability to assert positively that an ailment is not carcinomatous, in the presence of certain forms of gastric disease of insidious and seemingly grave nature, occurring in the middle period of life, of neural or inflammatory origin, the symptomatology and course of which so often intimately suggest a malignant growth.

The early idea that the absence of HCl from the stomach-contents was diagnostic of carcinoma, which arose through the investigation of von den Velden, unfortunately could not be subsequently confirmed, and it is now generally recognized that in a large number of diverse gastric affections, primary or symptomatic, free HCl may be either temporarily or permanently absent. The memory of the once grave import attached to this sign when free HCl was absent for at least a considerable time, in the face of pronounced symptoms, and at an age when the occurrence of carcinoma was possible, and the earlier errors in judgment not infrequently so originated when faith in this indication was strong, should lead one to examine very critically the evidence concerning this new dictum of Boas, which, if true, is so valuable.

With these thoughts in mind I have concerned myself with an examination of the matter since becoming aware of Boas' earlier results. My desire has been to investigate impartially the subject before saying a word concerning it, and then presenting finally personal evidence *pro* or *con* that could be regarded as conclusive. Unfortunately for my purpose, in the past sixteen months a dearth of that ample and suitable material from which data for conclusive opinion could be finally given, and the too brief time that has elapsed for such positive judgment, do not allow of report now. I regard it essential to direct attention to the subject thus prematurely, however, in order to bring to the notice of the readers of THE MEDICAL NEWS some results of Boas' work, for the purpose especially of correcting a misapprehension that may have been created by some remarks in a paper recently published in these columns, on "The Treatment of Lactic-Acid Excess in the Stomach."[1] In this paper the author, referring very briefly to the result of Boas' valuable investigations, and presumably familiar with the technique employed by the latter, remarks that his own experience entirely negatives Boas' conclusions. He then specifically states that, unlike Boas, he has encountered lactic acid in the stomach, not only during the first part of normal digestion, but also under abnormal conditions, whether these are accompanied by persistent diminution in the secretion of HCl, or in its absence, and in such affections as sluggish motility and gastrectasia, with or without malignant disease, especially when so situated as to cause stenosis.

Although it is evident to me, it cannot be to those not familiar with Boas' work, that the author of this statement has not employed Boas' technique, and is unaware of the very grave errors and utterly useless results that must arise from such inattention, naturally leading to misapprehension and tending to bring the praiseworthy investigations of Boas, from which so much may be expected, into early and undeserved discredit.

---

[1] Entitled, "The Occurrence and Diagnostic Value of Lactic Acid in the Stomach," Münchener medicinische Wochenschrift, October 24, 1893.

[1] By Dr. A. A. Jones.

The past researches of Ewald and Boas, as is well known, indicated that fermentation lactic acid[1] is regularly formed during the early stage of normal gastric digestion, and that its inhibition and final disappearance occur only in the presence of some amount of unsatisfied free HCl,[2] and this is still accepted by the many who similarly cling to the ancient idea that lactic acid is a very common accompaniment of the fermentative processes of chronic gastritis and other affections of the stomach, in which there is great diminution in or absence of free HCl. This view was dominant until the recent researches of Martius and Lüttke on HCl-determinations in the stomach, during which these investigators first showed that lactic-acid formation does not occur normally in the stomach, as was supposed, and that, moreover, it is absent under conditions in which its presence had been supposed to be quite constant. Previous erroneous results originating the former view have apparently arisen through either trial-meals having been given that contained preformed lactic acid or its compounds, or through sources of error not then apparent in the application of the tests for lactic acid. The results of Martius and Lüttke were so constant as to the evidence of absence of lactic acid both in normal gastric digestion and in chronic gastritis that Boas, in view of these, instituted a reinvestigation of the whole subject. As concerns the former of these points, Boas soon ascertained the highly significant fact, perhaps explanatory of former contrary results and of those of a contrary nature obtained by Dr. Jones,[3] referred to, that *all products of the bakery contain, preformed, an appreciable amount of lactic acid.*[4]

Adopting a form of trial-meal[5] from which error could not arise—a flour-soup, the ethereal extract of which was found not to contain even the minutest traces of lactic acid or lactates—and taking the precaution, first, to cleanse by lavage the stomach in any case in which retarded propulsion would permit remnants of a former meal to be present and falsify the issue, his results have been invariable that not only is lactic acid not present at any stage of normal digestion, whether free HCl be absent or not, but that *it is constantly absent also in all affections of the stomach save carcinoma.* Boas, moreover, found that in the latter lactic acid is usually present during the digestive process in such amounts and at such an early period that by its recognition the ailment may be readily diagnosticated, when other symptoms, such as tumor and increasing cachexia, are yet absent and strong hope exists for a cure by operative means.

Researches in Boas' clinic were made on all types of chronic diseases of the stomach, with the exception of ulcer, in the latter of which Boas naturally regards it as inexpedient either for diagnostic or therapeutic purposes to employ the tube. These cases include a large number of atony, chronic gastritis, pyloric stenosis with consecutive dilatation, and, finally, carcinoma. *In all of these, with the notable exception of the last, even although in the non-malignant cases with pyloric stenosis the trial-meal was allowed to remain over night in the stomach, and marked fermentative processes had occurred, with the presence of sarcinæ, yeast-fungi, hydrogen sulphid, acetone, and the like, lactic acid was always absent.*

In marked contrast to this were the results in the cases of carcinoma. In twenty out of the twenty-one cases studied, whether encountered before the presence of tumor or subsequently, lactic acid was constantly present in such an amount as to give a marked reaction to such a coarse test as that of Uffelmann. In the greater number of these cases there was delayed propulsion, the stomach containing in the morning the remnants of food ingested the evening before. This was especially noted even in the early stage in those cases in which the lesser curvature was afterward shown to be the seat of the growth. In all of the twenty-one cases free HCl was constantly absent. A strikingly interesting feature that forcibly illustrates the practical diagnostic value of Boas' observations, if further fully confirmed, is the fact that four of these cases came under observation at a very early stage, before any indication of tumor was detectable, and that a diagnosis made by the lactic-acid finding was fully verified by the subsequent development of the characteristic symptoms, including the presence of tumor, and in one of the three, still later, by a necropsy.

This last case is probably that referred to by Cohnheim, of Boas' clinic, in an interesting paper[1] on the early diagnosis of gastric carcinoma. This case is of such striking interest that it merits brief mention here as illustrative of the value of this new diagnostic point.

The patient, a male, forty years old, presented himself at the Polyclinic in Berlin during April,

---

[1] As distinct from sarcolactic acid existing in flesh.

[2] From 0.01 to 0.07 per cent.

[3] That is, accepting that all sources of error in the application of the tests for lactic acid were eliminated, as is, of course, to be supposed.

[4] Boas' words are: "Allein es hat sich gezeigt—und das ist ein cardinaler Punkt—dass sämmtliche im Handel vorkommenden Gebäckarten mehr oder minder grosse Mengen Milchsäure präformirt enthalten. Alle meine Versuche, mir ein absolut milchsäurefreies Gebäck zu verschaffen, blieben resultatlos."

[5] This consisted specifically of a thin gruel made of a tablespoonful of oatmeal flour to the liter of water, and flavored with salt.

[1] Deutsche medicinische Wochenschrift, May 17, 1894.

1892, with symptoms that first led to the diagnosis of gastric ulcer, on which account examination of the secretory function of the stomach was made. He at first improved on the treatment instituted, and the painful areas, anteriorly and dorsad, suggestive of ulcer, disappeared. Shortly afterward he again returned for treatment, with renewed symptoms, including repeated vomiting. A gastric examination was now made and disclosed absence of free HCl; very pronounced presence of lactic acid, and marked stagnation of the ingesta, but without as yet decided dilatation of the stomach. These findings were obtained with all subsequent—a good number of—tests made. Although no tumor was apparent by the end of May, 1892, Boas diagnosticated gastric carcinoma, from the fact of the decided amount of lactic acid always present, the total absence of free HCl, repeated vomiting, decided loss of flesh, and the development of pronounced symptoms of gastric disorder without demonstrable cause.

Under lavage decided improvement occurred, and after two-and-a-half months' treatment the patient was discharged. Two months subsequently (August, 1892) symptoms had recurred, loss in weight continued, and some cachexia had now appeared. The liver was apparently enlarged, yet no tumor was appreciable to palpation. He was again lost sight of, but was finally seen in December, 1892. He then had lost eighty pounds in flesh. The vomit was at times of a "coffee-ground" appearance; there was edema; some swelling of the inguinal glands; fissured, uncoated tongue; a weak, easily compressible pulse. Between the right sternal and parasternal lines, halfway between the xiphoid process and the umbilicus, could now, for the first time, be felt a tumor that seemed to spring from the liver. The stomach was not enlarged to inspection, and no splashing sound was to be obtained. By percussion the greater curvature was found to occupy the umbilical region. The patient shortly afterward died. A necropsy revealed a hard tumor, the size of an apple (an adeno-carcinoma, rich in connective tissue, ulcerated on its mucous surface), occupying the pyloric region and sharply defined from the remainder of the stomach. The pylorus was patent to one finger. The tumor had not been demonstrable to palpation until late in the course of the ailment, because of its being entirely covered by the liver. Resistance in the region of the gall-bladder, which had been felt and which had been regarded as a metastasis to the liver, had been produced by this tumor so overlapped. This error, considering the unusual position of the growth, was venial.

These results, in the hands of so competent an observer as Boas, very naturally interested me greatly, as my own work lies so largely in a similar field. Although I am as yet unprepared to offer the data I have obtained from an investigation of the subject to the present, because, as remarked, of paucity of material and prematureness of opinion, I may rightly state here that thus far my observations are all in support of Boas, and I have come to feel that much may be expected from this new diagnostic sign.

Apart from its obvious practical positive value, my present experience indicates that it may be regarded of the greatest utility from a negative standpoint, although it is, perhaps, early to speak very positively as to this now. I can at least say that it has stood me in good stead on more than one occasion already. It will be of interest and profit to relate that more than a year ago, when I began routine examinations for lactic acid after Boas' method, and following his technique, I failed to obtain reactions for it in gastric ailments obviously, without this test, not carcinomatous, and I likewise obtained persistently negative results in several cases which then presented, as regards the usual clinical picture, symptoms among not the least of which were loss of weight, more or less cachexia, and a favorable age, strongly suggestive of incipient malignant disease of the stomach. But the continued absence of lactic acid enabled me to take a more hopeful view, which the sequel has in each case supported.

One of these cases is worthy of notice here. It is that of the mother of one of my former clinical assistants, brought to me in November, 1893, for an opinion because of the gastric ailment being regarded by an earlier attendant as of the nature of possible malignant disease.

The patient, forty-seven years old, who for several years past had had dyspeptic symptoms, developed, somewhat less than a year previously to my seeing her, more or less continuous gastric pain, increased by food often of the plainest sort; there were constipation and vomiting; anorexia was complete, and she had lost much flesh within a few months. This last was apparently largely due to the fact that she had been kept upon a strictly milk diet for a long time. She had frequent attacks, lasting for from some hours to one or two days, in which there was great prostration, with dyspnea, an almost extinct pulse at the wrist, and a very feebly acting heart. When not suffering from these attacks the heart was in fair condition, with a pulse of moderate tension. The patient was highly anemic, somewhat emaciated, with what then seemed a trace of cachexia. The teeth were very imperfect, the breath foul from the latter, and the tongue usually slightly furred. Constant salivation was present. The epigastric area was tender to pressure, slight or deep, and, apparently, more so at the site of the greater curvature and near the pylorus. No evidence of tumor was obtainable. The stomach showed slight dilatation by auscultatory percussion, reaching, when only slightly distended with air and otherwise empty, to within an inch of the umbilicus. The area of liver dulness was normal; no displacement of the right kidney existed. The urine was free from albumin; urea was normal in amount.

Several gastric examinations made within a few days of each other all showed: Absence of free HCl; no Günzburg's response until from (variously on different occasions) 0.5 to 2 c.c. of $\mathrm{HCl}\frac{N}{10}$ were added to 10 c.c. of the filtrate. Total acidity, usually from 20 to 30. Digestion-test was but slightly positive in from eight to ten hours, even with the addition of HCl up to 0.2 per cent. free acid. The lab-test was delayed (upward of five hours) in the incubator. The labzymogen-test was positive only at the end of one hour. Gastric propulsion was sluggish; one-and-a-half hours after an Ewald trial-breakfast (a roll and 300 c.c. water) upward of 160 c.c. could be removed. On alternate occasions there were given the baker's-roll breakfast and that of from two-thirds of a pint to a pint of thin gruel. With the former a slight lactic-acid reaction was usually obtained, while with the latter no traces of lactic acid even existed.

Jaworski's test showed no pronounced atrophy of the secretory structure.

Diagnosis: Aggravated chronic gastritis, perhaps originated by the condition of the mouth.

The patient was at once sent to a dentist, and, as her strength permitted, the bad teeth were removed and the mouth put into order.

I instituted a very carefully regulated diet; at first very easily digested, and often of predigested food. Systematic daily lavage was begun, Carlsbad salts were given for constipation, and codein, cannabis indica, and belladonna, for periods of a few days, were used for gastric pain; and the belladonna also to control salivation. At first, for a time, and later for shorter intervals, dilute HCl was administered before meals when predigested food was not given. At the outset it was employed in small, and subsequently in large doses, when nitrogenous solid food was eaten, as a stimulator of secretion and motility. An active preparation of papain was used after meals. Later, to assist in remedying the anemia, the mixture of iron carbonate was given in teaspoonful-doses after meals, and strychnin and nitro-gylcerin were employed for the attacks of prostration. Improvement was soon apparent in the subjective symptoms. The appetite returned somewhat. Pain was no longer continuous, but occasionally it was as severe as before; on pressure it had also lessened, and vomiting was less frequent. The tongue soon cleared, and fetor of the breath disappeared, as did finally all tendency to salivation; but at the expiration of four months there was no alteration in the condition of the secretory function of the stomach, although propulsion had slightly improved. Daily lavage could not be continued steadily, because of the exhaustion its practice occasioned, and cascara was substituted for the Carlsbad salts, to remedy the constipation, on account of the salts apparently aggravating the gastric pain. Secretion of free HCl being still lacking after a number of months of the foregoing treatment, intragastric galvanism and faradism were begun and continued in combination, and after several weeks faradism alone for some two months, with still no decided change in secretory function. She was then removed to the seashore. After a few weeks, during which I did not see her, I was informed that although she looked better she still had gastric pain, occasionally vomited, and that on several occasions during morning lavage, while fasting, a little blood and a few particles resembling small pieces of tissue were seen in the water. Unfortunately, these latter had not been saved for examination. When seen later—in August, 1894—her weight was still eight pounds less than in the winter, probably partly due to change in weight of wearing-apparel. Nothing had been noted in the wash-water for some time. Appetite then was moderate. Epigastric pain and tenderness persisted, but were less in degree than formerly. No tumor was evident and no cachexia. Lactic acid and free HCl were still absent.

This case in several of its features strongly suggested the possibility of one form of latent gastric carcinoma, and had the result of the non detection of lactic acid been contrary, with the coincident steady absence of free HCl under treatment likely to promote its return, I should have regarded it as within the range of probabilities and given a gloomy prognosis. Since the end of summer steady improvement has occurred under the use of full doses of HCl, strychnin, iron, and lavage twice or thrice weekly, and when recently seen the woman presented no indications suggestive of grave disease, although free HCl has not returned.[1] She had regained all the weight lost; had a good color and a good appetite and ate and digested well through the aid of HCl or papain.

The method employed by Boas for the detection of lactic acid in the earlier part of his experiments was the color-test of Uffelmann, so generally used for a like purpose everywhere, because of its simplicity of application and, when certain very important precautions are observed, its accuracy.

A large series of experiments in Boas' clinic convinced him that no color approaching that of the lactic-acid reaction save a *decided* citron-greenish yellow (Cohnheim), or a canary-yellow,[2] could be depended upon; and the fact must be borne in mind that a considerable number of substances react to the ferric-chlorid test in a manner approaching the response of lactic acid, although not so intensely or with the same hue. A differentiation may, therefore, be made by one practically familiar with this color-test. Such substances as acid phosphates, sugar, alcohol, tartaric acid, encountered constantly or occasionally in the stomach-contents, may all mislead the unwary. When this test is employed and a positive reaction is obtained, it is always essential to exhaust a portion of the gastric filtrate with ether, and further test an aqueous solution of the residue. By this means all sources of error, save alcohol, are removed.[1] Great care must be exercised in the application of such an apparently simple test even as that of Uffelmann or its modifications, and the judgment of none without some practical training in chemic manipulation and acquaintance with the shades of color yielded by varying amounts of lactic acid and its simulators is to be depended upon. Especially is this the case when so much hinges upon an opinion in a matter so weighty as the determination of the presence of lactic acid now becomes.

---

[1] An examination after the flour-soup meal at the date of this writing gave the following: One-and-a-half hours after the trial-breakfast, the stomach having been washed the evening before, 100 c.c. were removed by aspiration; the gruel well solved, t. a. = 24; no response to freshly-made Günzburg's solution; no traces of lactic acid. Lab-test positive in one hour; lab-zymogen within one minute. Because of the quantity of filtrate used for the lactic-acid experiment, sufficient was not left for the digestion-test or for examination as to bound HCl.

[2] Boas speaks of the special hue of these decisive colors as either *saturated canary-yellow* or a *zeissig-yellow*. Any other coloration cannot be regarded as conclusive.

As regards negative results, error may also arise. Ewald speaks of such an observer as Cahn, of Strassburg, who could not at first confirm Ewald's findings as to the presence of lactic acid in the digestion of meat.

The sources of error with Uffelmann's reagent and its lack of delicacy, the inability to depend upon a response unless of the characteristic color mentioned—to produce which its presence in some amount is required—finally led Boas to seek another method that would be of value clinically as well as more exact chemically, and at the same time of far greater delicacy. He finally perfected such a method, which is simple of application, especially when qualitative results only are desired. This method is based upon the fact that when substances containing lactic acid are carefully heated with oxidizers, such as manganese dioxid and sulphuric acid, the lactic acid is decomposed into formic acid and acetic aldehyd. The presence of the last is readily determined by a number of tests. Boas regards the iodoform-test as well suited for both qualitative and quantitative work. By it, the aldehyd conducted into an alkaline solution of iodin forms iodoform. A quantitative examination is possible by this method from the fact that under proper precautions a definite amount of aldehyd decomposes a given quantity of iodin-solution. Ketone and alcohol, which both react similarly, are readily eliminated by first concentrating the filtrate to be tested to a syrupy consistence. As carbohydrates, similarly treated with oxidizing agents, also yield aldehyd, a watery solution of an ethereal extract[2] of the condensed gastric filtrate, of a non-lactic-acid-yielding trial meal, must alone be used in the experiment. Special treatment is also required of the filtrate before concentration, should it show the presence of free acids to congo.[1] As this test properly applied is without sources of error and its manipulation is most easy to one accustomed to chemic work, and it is, moreover, one of great delicacy, it should undoubtedly supplant the old uncertain method of Uffelmann or its modifications.

The scope of this paper—intended merely as a preliminary note and already too lengthy—does not admit of discussion of the most interesting problem as to the cause of the gastric formation of lactic acid only in carcinoma: Whether it be through the production of a lactic-acid enzyme, by the specific agency of the carcinoma, or through the latter alone favoring the abundant development of lactic-acid-generating micro-organisms, probably derived from the mouth, of which more than one variety exists. This question, so interesting and important, will receive due attention in a subsequent paper.

THE INDICATIONS FOR AND THE NATURE OF TREATMENT IN SEVERE ABDOMINAL INJURIES AND INTRA-ABDOMINAL HEMORRHAGE, UNACCOMPANIED BY EXTERNAL EVIDENCE OF VIOLENCE.[2]

By JOHN B. DEAVER, M.D.,
PROFESSOR OF SURGERY, PHILADELPHIA POLYCLINIC; ASSISTANT PROFESSOR OF SURGICAL ANATOMY, UNIVERSITY OF PENNSYLVANIA; ATTENDING SURGEON TO THE GERMAN AND PHILADELPHIA HOSPITALS; CONSULTING SURGEON TO THE GERMANTOWN, ST. TIMOTHY'S, AND ST. AGNES' HOSPITALS.

Every surgeon has undoubtedly at some time in his experience, either in private or hospital practice, met with cases of the class covered by the title of this paper. These are cases in which the history and general condition of the patient give the impression that there is a serious lesion within the abdomen, and yet, upon examination, we find total absence or only slight evidences of injury. The tendency, I fear, with many is to treat these patients tentatively, only to be awakened at the autopsy to the fact that a rupture or a tear existed in the abdominal cavity, which could have been relieved by early radical operation.

The mortality in these cases is appalling. References to the literature of the subject will amply bear out this statement, which is readily accounted for by the nature of the injuries. When the lesion is of the liver or spleen, if the patient does not die of shock or hemorrhage, a violent peritonitis supervenes, to which he shortly succumbs. If the liver, spleen, or kidneys are involved, death from hemorrhage may ensue in a very short time. Should the stomach, intestine, or bladder be ruptured, and its contents poured into the peritoneal cavity, death from peritonitis will result. In rupture of the mesentery the danger is from hemorrhage, yet, when the opening in the mesentery is small, a clot may form sufficiently large to control the bleeding. Should death occur under these circumstances it would be the result of peritonitis, caused by free blood in the peritoneal cavity. I shall report a case of this character in which recovery followed immediate operation. In ruptured extra-uterine pregnancy death is due either to hemorrhage or to peritonitis.

---

[1] It must be remembered that all preparations of ether, save that especially obtained without, contain considerable alcohol.

[2] Prepared with an absolutely alcohol-free ether.

[1] This excellent method I mention here in outline only. The process itself is treated in detail in a paper by Boas in the Deutsche medicinische Wochenschrift, September 28, 1893.

[2] Read before the Philadelphia Academy of Surgery, January 7, 1894.

The usual history of these cases, with the exception of those of extra-uterine pregnancy, is that the patient has received a direct injury to the abdomen, which is found to be unaccompanied by external evidence. These injuries may result from railroad accidents, from being caught between cars, or from blows upon the abdomen received in various ways.

This class of injuries is quite common in military surgery, more so in the past, when spherical balls were used with only a low velocity. A majority were supposed to be caused by the violence of the wind displaced by the passing ball; but we now know that they were due to the impact of balls almost entirely "spent." Two cases that illustrate this occurred at the siege of Sebastopol. In neither did the clothing or the abdominal walls show any signs of injury, but in both the liver and spleen were comminuted to a pulp, and the intestines were extensively lacerated.[1] As yet we have had no reports from the surgeons of the armies engaged in the present strife between Japan and China, but it will be of great interest to read the records of such cases. We can expect, I think, a very full and detailed account from the Japanese surgeons. We have all applauded the work of some brilliant individuals of the Japanese profession, and, in fact, we must assign to Japan in medicine the same standing that she has taken in other walks of civilized life, and which she has demonstrated she can hold.

The most prominent symptom is pain, which is accompanied by shock, the degree of which is dependent upon the extent of the injury and the temperament of the indvidual.[2]

The pain is peculiar, and difficult to describe, but is readily recognized by one who has seen many of these cases, and by the patient himself. It is not that of ordinary intra-abdominal affections, but is described by the patient as if something had given way or ruptured, and is usually accompanied by a consciousness of impending death. It is usually accompanied by tenderness, which will be more or less localized, unless the ensuing peritonitis be general. In the early stages of the injury, when shock is most profound, the pain may not be so pronounced, and if large doses of opium be administered it may be masked throughout the course of the trouble. When vomiting is present it is usually associated with pain. Rarely does the vomited matter contain blood. There is often seen a characteristic rigidity of the abdominal walls which is due to intra-abdominal irritation. I have seen this so pronounced as to recall to mind the checker-board appearance of the normal abdominal walls as represented in the pictures of the early artists.

In the cases I have observed, consciousness has invariably been preserved for varying periods of time. Restlessness is not usual in the early stages, except in severe hemorrhage; but later on, when peritonitis develops, it is not an uncommon symptom. The pulse and temperature vary according to the degree of shock. The former is weak and running, varying from 100 to 160, and the temperature is subnormal. If reaction take place, the pulse becomes stronger and less frequent, and the temperature reaches the normal line. After reaction peritonitis is invariably the rule, and is accompanied by an accelerated pulse of high tension. The temperature under these circumstances is unreliable, as it does not correspond to the degree of inflammation or of septic infection. A high temperature with a slow pulse is less significant than a rapid pulse with a low temperature. In cases of septic peritonitis, in which autopsy has revealed a belly-cavity full of foul pus, I have seen the temperature run a normal course throughout the disease.

The part the sympathetic system of nerves, which has its largest distribution in the abdominal cavity, may play in injury to the abdomen is important in considering the differential diagnosis between simple contusion and contusion accompanied by visceral lesion. In the former, the absence of the severe and characteristic pain, of constant and persistent vomiting, of the anxious expression and presentiment of impending death, and of any evidence of loss of blood, associated with the occasional presence of suddenly developed meteorism, will usually be sufficient to establish the differential diagnosis. This condition of meteorism is due to paralysis of the muscular coat of the bowel consequent upon the concussion of the plexuses. There are cases, however, in which it is very difficult to say definitely whether there be a visceral complication or not. Under these circumstances one can only wait for a comparatively few hours, when, if improvement is not apparent, the operative course is to be pursued. When the solid viscera are the seat of injury, hemorrhage will be the main source of anxiety. The pain and the exsanguination give the clue. If the patient should react, which is unusual unless the kidney is the injured organ, we shall find in addition dulness on percussion in the flank. Rectal or vaginal examination may afford aid in determining the presence of a collection of blood in the pelvis. The solid organs suffer most from external violence on account of their fixity, density, and close proximity to the bony structures. The liver is the most often injured, then the uterus, the spleen, and the kidney, in the order named. The stomach is least often injured, there being very few such cases on record. Dr. J. W. Goff (*Medical and Surgical Reporter*, 1892) reports a case of ruptured stomach following a horse-kick of the abdomen, and verified by an autopsy. The shock was profound, and there was vomiting with an absence of blood. The author states that he believes immediate operation would have saved the patient's life.

---

[1] Mr. Hulke, Lancet, December 31, 1892.

[2] I may say here that temperament and nationality have a strong bearing on the production of shock. Persons of a highly nervous temperament suffer more from shock than do phlegmatic individuals. For example, Americans are far more liable to suffer a severe degree of shock following injuries or operations than are Germans.

In the *Glasgow Medical Journal* for 1894, volume xli, Andrews reports a case of rupture of the stomach without external evidence of violence, in which all the symptoms of a serious visceral lesion were present, with the exception of vomiting. The rupture was in the anterior wall, was about an inch long, and involved all the layers. I cite this case as one of special interest, on account of the location of the tear and the absence of vomiting.

The liver is the organ most often affected, because of its position beneath the ribs and against the spine, and because it is held firmly in place by strong ligaments and bloodvessels. It is most commonly ruptured on its upper surface, generally in the right lobe, and in a majority of such cases the injury proves fatal. Dr. H. P. Loomis (*Medical Record*, January, 1893) reports a case in which the patient was struck on the right side by a pole protruding from the back of a wagon turning a corner, without external evidence of violence. There was a 3-inch tear in the right lobe of the liver and a pint of blood in the abdominal cavity. The patient died in the street from hemorrhage, before medical aid could reach him.

Mr. Battle (*Lancet*, 1894) reports a case of rupture of the bile-duct in a boy, six years of age, who was run over by a hansom cab, and in which there was but slight shock, without much pain or tenderness. Vomiting began early and persisted. On the fifth day slight jaundice developed. An operation was performed on the eighth day, and the abdominal cavity was found filled with bile. The boy died on the morning of the ninth day. At the autopsy the liver and gall-bladder were intact, but about one-half an inch beyond the junction of the cystic and hepatic ducts the common duct was found to be torn completely through. No other injury was found.

J. E., aged forty-six years, was admitted to the German Hospital on November 17, 1893, suffering from injuries received by being struck by a locomotive. He had a compound fracture of the lower jaw, lacerated scalp-wounds, and fracture of four ribs on the left side, with no other signs of injury. He died six hours later. The post-mortem examination revealed hemothorax of the left side. The peritoneum was not perforated or otherwise injured, but the peritoneal cavity was filled with blood. The spleen was completely comminuted, and the left kidney had been forced from its bed and was floating in the retro-peritoneal space. There was an extensive hemorrhage between the layers of the mesentery and a hemorrhagic extravasation in the posterior wall of the stomach.

H. M. C., colored, aged sixteen years, was admitted to the German Hospital on the evening of December 3, 1894. While playing about some moving freight cars he had been accidentally caught between the bumpers, sustaining an injury of the abdomen. Examination upon admission failed to disclose any evidences of external injury. The introduction of a catheter gave exit to clear urine. There was a moderate degree of shock, and the patient complained of severe pain in the abdomen and tenderness upon palpation. Further investigation proved negative.

The resident surgeon, not deeming the case of sufficient severity to send for me, treated the patient for shock. When I examined him the following day, it was very evident from the severity of the abdominal pain and tenderness, associated with very decided rigidity of the abdominal walls, that the patient was suffering from a serious intra-peritoneal lesion. I decided to open the abdomen at once. As soon as the peritoneal cavity was opened a large quantity of dark liquid blood escaped. The small intestines were delivered, when the cause of the lesion was found to be a ruptured mesenteric vein, the bleeding from which was arrested by the presence of a large diffused blood-clot occupying the interval between the layers of the mesentery. To make sure that there was no other lesion, the large intestine, the stomach, the liver, and the spleen, were carefully examined, but with a negative result. The abdominal cavity was washed out with warm saline solution, glass drainage was introduced into the pelvis, and the wound closed. Recovery was uninterrupted.

L. C., male, an Italian, aged thirty-five years, was admitted to the German Hospital with a history of a fall of about 50 feet, striking upon his abdomen. He was profoundly shocked and exsanguinated. The only external evidences of injury were some slight cuts on the hands and head. A diagnosis of internal hemorrhage was made, and the abdominal cavity was opened. Dark liquid blood escaped as soon as the peritoneum was opened, and the source was found to be the mesenteric vessels. The mesentery was torn half-way across, and the intestines were lacerated in four places. The mesentery was united by a series of catgut ligatures, and the rents in the intestines were closed with Lembert sutures. The abdominal cavity was washed out with hot saline solution and closed. The man died two hours after the operation. The autopsy demonstrated several tears in the gut which had been overlooked, and several grapeskins and pieces of figs in the peritoneal cavity.

M. E., twenty-four years of age, a nurse, was admitted to the German Hospital, January 20, 1893. While lifting a heavy weight from an elevator she felt something give away in her abdomen. This was immediately followed by severe lancinating pain in the right ovarian region. She was menstruating at the time. Pelvic peritonitis promptly set in. An examination demonstrated a tumor in the right broad ligament about the size of a hen's egg. The peritonitis and tumor subsided under treatment, and she made a slow recovery. Diagnosis: Pelvic hematocele from rupture of an engorged ovarian vein.

The most common form of intra-abdominal hemorrhage is that resulting from ruptured extra-uterine pregnancy. While these cases may be due to traumatism without any external evidence, they are usually spontaneous. While hemorrhage from the pelvic organs of the female usually occurs from a ruptured extra-uterine gestation-sac, it may be due to other non-traumatic causes. Hematosalpinx may occur independently of pregnancy, and rupture either spontaneously or from traumatism. Again, degenerated bloodvessel-walls, and especially veins, may rupture under similar circumstances. Hemorrhage itself is seldom the cause of death, but, associated as it is with shock, the degree of which is out of all proportion to the severity of the accident, it is frequently fatal in a very short time. When the peritoneum is wounded, shock is still more profound, and is of the type known as peritoneal shock. Hemorrhage within the peritoneum is sometimes very slight, and distinctly localized, and may occur several times during the course of the illness. It may take place between the layers of the broad ligament, and soon stop from the pressure.

I report the following two cases of hemorrhage from my list of operations for ruptured extra-uterine gestation-sacs, as they illustrate so typically the wisdom of immediate operation:

Mrs. A. K., aged thirty-one years, was admitted to the German Hospital, September 21, 1894, with the following history: For six months prior to admission she had been subject to attacks of vertigo, pain in the back and limbs, and for six weeks there had been a constant bloody vaginal discharge. Examination revealed a retroflexed uterus, with a slight tear of the cervix, and the presence of a small movable mass behind and to the left of the uterus.

On September 25th, four days after admission, the patient was etherized, and the uterus was dilated and curetted. After the operation the discharge stopped, but the patient gained strength very slowly. She was advised to submit to abdominal section, but preferred to wait until she was stronger. On the night of November 22d she awoke with a severe pain in the right side, and on attempting to walk to the water-closet fainted. After returning to bed she again fainted, and went into collapse, the pulse becoming almost imperceptible, and the temperature falling to 96°. Under active stimulation she reacted. The diagnosis was made of internal hemorrhage from rupture of a probable extra-uterine gestation-sac.

The abdominal cavity was found filled with fluid blood and clots, and the right tube ruptured. The tube was ligated, and the abdominal cavity flushed with hot saline solution, a glass drainage-tube introduced, and the wound closed. The patient was not much shocked by the operation, but on the contrary seemed rather improved. The drainage-tube was removed on the third day; the wound healed by first intention; and the patient made a good recovery.

Mrs. J. W., aged thirty-six years, was admitted to the German Hospital, November 21, 1894, with the following history: About 2 o'clock on the morning of admission she was seized with violent pain in the lower abdomen. For this she took some whiskey, and was somewhat relieved. At 9 o'clock the same morning she started for market, and was suddenly taken sick, becoming very weak, and suffering from violent pain in the abdomen. She returned home with difficulty, and summoned Dr. Hand, who advised immediate removal to the hospital. At the time of admission she was very weak, and there was distinct tenderness over the abdomen, with slight dulness on the right side. Immediate operation was advised and assented to. When the peritoneal cavity was opened it was found to contain fluid blood and clots. The right tube was the site of a small rupture, and was ligated and removed. The abdominal cavity was washed out with hot saline solution, glass drainage-tube was introduced, and the wound closed. The patient was very much shocked by the operation and reacted slowly. During the operation hypodermoclysis was practised. The drainage-tube was removed on the fourth day; the wound healed by first intention; and the patient was discharged, well, on the twenty-third day.

The following case of hemorrhage from ruptured extra-uterine gestation-sac illustrates the danger of delay as strongly as do the two previous cases the efficacy of prompt interference:

Mrs. P., aged thirty years, was the patient of Dr. S. Cooke Ingraham, of Wissahickon, this city, who furnished the following history:

I first saw the patient on January 29, 1892. She complained of severe abdominal pains of a bearing-down character, and of a sense of fulness in the epigastric region. She had been married seven years, but had never been pregnant, and laughed at the possibility. For the past three years the menstrual flow had been decreasing in amount, and for several months past had been very scant. The breasts were slightly enlarged, but the areolæ were not darkened. The glands of Montgomery were a little more prominent than normal. She had suffered from morning vomiting for the past month.

I was hastily summoned to see the patient on the morning of February 2d, and found her in a state of collapse, pulseless, and with a temperature of 96.5°. She reacted to active stimulation, and was sent to the German Hospital for immediate operation, a diagnosis of ruptured extra-uterine gestation-sac of the tubal variety having been made. Upon admission her pulse and temperature were normal. She did not complain of pain. Examination through the abdomen and by the vagina and rectum failed to reveal any mass, although a circumscribed area of flatness could be demonstrated low down and to the right side. She continued in this condition until February 12th, when, at her own request, she was discharged. On February 23d she was readmitted at Dr. Ingraham's earnest request. At the time of the second admission the abdomen was markedly distended, being tympanitic above and flat below, the pulse 116, temperature 101.5°. The woman complained of considerable pain.

The following day she was operated upon, and when the peritoneum was opened a fetus with clots and fresh blood gushed out. The ruptured sac occupied the right iliac region, and was tightly adherent to the neighboring coils of small intestine, to the cecum, and to the vermiform appendix. After a prolonged and tedious dissection the sac was enucleated. This was accompanied by very free bleeding, which necessitated packing of the cavity with gauze. The wound was closed with the gauze packing *in situ*. The patient died the following day of hemorrhage.

The immediate effects of an injury severe enough to cause a serious lesion of an abdominal viscus are sometimes so slight as to be misleading. Very often a patient with such a condition will walk to a conveyance or to the hospital, complaining only of a slight pain. In varying periods of time following the injury more decided symptoms will develop, viz., signs of hemorrhage if the solid organs be involved, and early peritonitis if the hollow viscera be ruptured or torn sufficiently to allow their contents to escape. When this occurs operation is imperatively demanded without delay. This is also true of hemorrhage consequent upon the rupture of an extra-uterine gestation-sac, be it traumatic or spontaneous. In ectopic gestation operation will be necessary in every case at some period in its history; therefore, if a diagnosis can be made or if even a well-founded suspicion of the condition exists, rupture should not be allowed to occur. If rupture does occur, however, immediate operative intervention is the only certain means of saving the patient's life. The longer the operation is deferred the greater the risk to life. Hasty operations, often necessitated by the patient's condition, are likewise less liable to reach a favorable termination. Blood-clots or intestinal or gastric contents cannot be washed out of the peritoneal cavity except by prolonged and repeated flushing.

The almost universal fatality of intra-abdominal lesions of traumatic origin is so well recognized that it seems as if there could hardly be any question as to the wisdom of opening the abdominal cavity. I would not be understood as meaning that abdominal section should be resorted to as a means of diagnosis; on the contrary, I believe that every known means, with attention to the most minute details, should be exhausted in establishing a diagnosis. When a diagnosis is impossible, abdominal section is justifiable only when it becomes the last and only chance for the patient.

I have refrained from using the terms exploratory and diagnostic incisions, believing that they not infrequently serve as a shield to cover a lack of diagnostic ability. It is a moral obligation resting upon every physician and surgeon to develop to the utmost of his ability the highest diagnostic attainments.

Aseptic surgery has undoubtedly been one of the greatest boons to humanity that the nineteenth century has brought forth. But to me it seems that it affords a great temptation to men who have not had experience and surgical training, and who have, therefore, not fully developed their diagnostic skill, to perform operations which are not necessary for the patients' good or with scientific precision.

CLINICAL LECTURE.

A CASE OF MYCOTIC ENDOCARDITIS.

By JAMES TYSON, M.D.,
PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

Gentlemen: The patient whom I present to-day is one of a class which unfortunately, often necessarily through difficulty of diagnosis, is recognized for the first time on the necropsy table. It is the case of a young girl, aged seventeen when first admitted to the hospital, December 7, 1893. She was born in Pennsylvania, and had been living at service previous to admission. Her family history is negative.

She has had the usual diseases of childhood, and when about eight years old had inflammatory rheumatism, and from that time has never been perfectly well. She says that every winter since she has had a return of rheumatism, and has been treated for heart-trouble more or less ever since her first attack. In the winter of 1892–93, after recovering from an attack of rheumatism and returning to work, she found that she had loss of power in the left arm and leg. On admission she complained of shortness of breath and a sense of tightness across the chest. She could not sleep lying down, because of palpitation and a feeling of suffocation. There was no edema of the feet or legs. There was evident loss of power in the left arm and leg, but sensation was unimpaired.

On physical examination, inspection noted a diffuse impulse in the neighborhood of the sixth interspace in the left mid-clavicular line; also a marked pulsation in the suprasternal notch. To palpation the apex-beat was found in the sixth interspace in the mid-clavicular line, strong and forcible, felt as far around as the anterior fold of the axilla. The impulse seen in the suprasternal notch was forcible to palpation, and a feeble thrill was felt at about the second interspace on the left side, and in the supra-sternal notch.

Percussion elicited relative dulness to the left of the sternum above the second cartilage as far as the parasternal line, and was succeeded by positive dulness at the third rib. The right border of the heart was found at the right edge of the sternum. Over the sternal region there was dulness from the second rib downward. Auscultation recognized a loud, rough steamtug murmur, loudest at the second interspace on the right side, the systolic element conducted into the neck, both murmurs downward along the left of the sternum, the diastolic louder, and toward the apex. Both were, however, lost before the apex was reached, while at the apex itself appeared a loud systolic murmur, conducted very strongly into the axilla, and heard also at the angle of the scapula.

The pulse on admission was 90; respirations, 25; temperature, 99° F., essentially normal. The urine-examination found the specific gravity 1030; reaction acid; albumin, a small amount, but no tube-casts.

On further examination of the left arm and leg there was found to be no atrophy, and when asked to describe the condition herself the patient said: "When the left leg is drawn up it seems heavy; the same is true of the left arm." Moreover, she could not raise her left arm to comb her hair. When she walked the left toe continued to touch the ground after it should have been above it. The loss of power followed an attack of rheumatism, during which she was confined to bed. She had been working, however, over a month after the attack before she noticed the loss of power, and while she seems to think it came on gradually, it is more than likely that it was sudden. The tendon-reflexes show marked increase, on the left more than on the right; and the slightest tap upon the radius or ulna produced intense reaction. There was, however, no ankle-clonus. She remained in the hospital until about the first of June, improving slowly, but always very nervous, excitable, and restless. Pulse-tracings made at different times during her residence in the house furnish typical tracings of aortic regurgitation. The diagnosis was aortic stenosis with regurgitation. Her temperature throughout her stay was normal, except for temporary and explainable causes.

She was readmitted on the 11th of October, 1894, with a report that she had been miserable all summer, and gradually getting weaker. About three weeks before admission she commenced to have chills, followed by fever and sweats. This occurred every day, the chill beginning in the afternoon; the fever reaching its acme in the evening. In the morning she sometimes felt warm, and was always very short of breath. She said her legs had been more or less swollen all summer, the left more than the right; that she had more or less rheumatism, which also seems to have been worse on the left side. Her left arm was still almost useless, and she complained much of pain in her left thigh and ankle. There was also great shortness of breath.

Blood-examination showed hemoglobin 45 per cent.; corpuscles, 2,880,000 in each cubic millimeter.

On the day of her readmission, October 11th, at 3 P.M., her temperature was 105.6°; her respirations, 32; her pulse, 120. At 8 P.M. of the same evening, her temperature was 97.6°; her respirations, 24; and her pulse, 74. At 4 A.M. the next day her temperature was 102°, and fell by 8 A.M. to 99.4°. A similar rise occurred at 8 P.M. of the 12th, followed by a fall to 99.6° by 4 A.M. the next morning.

Reëxamination of her heart recognized very much the same condition of physical signs as at her discharge, except that there was further enlargement to the right, and a double mitral murmur instead of the single murmur in the mitral area present at her first admission. Thus the signs now pointed to double mitral disease, as well as double aortic disease.

This extraordinary history of daily chill, fever, and sweats, with the signs of valvular disease, at once suggested the possibility of malignant endocarditis, and we sought at once to eliminate other possible causes of symptoms so marked and striking. Accordingly, her blood was exhaustively examined by Dr. Daland and ourselves without finding any malarial organisms. She was at the same time placed upon full doses of quinin, twenty grains a day, for a number of days in succession, without producing any effect upon the chills and fever. These continued daily, and there would be at times two periods of acme in the twenty-four hours, with this further feature that the maximum might be noted at four o'clock A.M. one day, and again at four o'clock P.M. the same day, with an intervening fall. Still, on the whole, it seemed that the highest temperature was reached more frequently during the latter part of the day. At this time, also, her blood was examined microscopically by Dr. Abbott and Dr. Ravenel, of the Laboratory of Hygiene, for micrococci, with negative results, while cultures also made at the same time remained sterile.

Reëxamination of the chest, on the 25th of October, 1894, noted a decided dulness from the ninth interspace downward to the edge of the thorax and below posteriorly to the spinal column, and anteriorly to the mid-clavicular line. There was also absence of breath-sounds in the same locality, and an absence of vocal fremitus; though it was noted, also, that there was little or no fremitus on the opposite side. With a view to determining whether this dulness was due to an enlarged spleen or a pleuritic effusion, a small trocar and canula of an aspirating apparatus were introduced a few days later in the ninth interspace just within the line of the angle of the scapula, with negative results. We concluded, therefore, that the enlargement was splenic, and probably due to embolism.

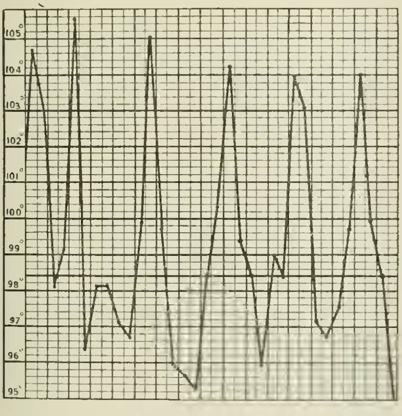
The patient's strength is rapidly succumbing to the exhaustive effects of the fever and the virulence of the poison. She is growing rapidly weaker, is anemic, almost bloodless in appearance, while the temperature-range has become even more marked and astounding, as revealed by the appended drawing of the temperature-chart.

It will be observed, for example, that at 10 P.M. of the 8th of November the temperature reached 105.4°, while by 4 A.M. the next morning it had fallen as low as 96.2°, a drop of 9.2°. By 6 P.M. it had again risen to 105°, followed by a fall to 95.2° at 4 A.M., or 9° in ten hours.

On the next day after the exploratory tapping there was a sharp pain in the abdomen, succeeded by diarrhea, which we suspected to be the result of another embolus lodged in some one of the intestinal bloodvessels, contributing, perhaps, to the extraordinary increase of the range of temperature noted.

For some days previously to November 13th there had been a small amount of albumin in the patient's urine and a few pale granular tube-casts. On this day, however, the albumin was found to be decidedly increased, and there were found in the urine numerous blood-discs and blood-casts, as well as pale granular casts. This was regarded as an indication that another infectious embolus had been shot off from the cardiac valves, and lodged this time in her kidney.

On the morning of November 14th, at seven o'clock, she called the nurse, and said that she could not move her right arm, and a few minutes later that she could not move her right leg; in a word, she was hemiplegic on the right side, the opposite of the primary attack of hemiplegia already noted as occurring previously to her first admission to the hospital. She remained conscious, and in the course of two hours there was complete return of motor power on the right side. The embolus was evidently small, and obliterated a vessel of corresponding size, whence the circulation was speedily reëstablished, and the hemiplegia was but transitory, while consciousness was not at all interfered with.



On the morning of the 15th two additional conditions presented themselves, also of great interest and importance. On her right hip was a large red blotch, nearly circular, two inches by two-and-a-half in diameter, evidently the seat of a blood-extravasation. Directly over the sacrum was another spot of the same size and character. This had occurred during the night, as at bedtime her skin was pure white and without a suggestion of discoloration. Evidently two emboli had been lodged in a bloodvessel of the skin, and the embolism was followed by the extravasation of blood beyond, constituting the well-known hemorrhagic infarct. During the next night another occurred in the same vicinity.

This history, including the chills, the marvellous temperature, the sweats, the signs of embolism in the brain, spleen, bowels, kidney, and skin, the rapidly growing anemia and general failure of health, in association with the signs of disease of both valves, admitted of but one conclusion, that the patient had mycotic or ulcerative endocarditis.

What, then, is mycotic endocarditis? It may be defined as an acute infectious fever due to invasion of the blood by a micro-organism and characterized anatomically by inflammation of the endocardium excited by the same organism. The disease itself has not been very long separated from others of like symptoms, except so far as the malignant nature is concerned. It was recognized as a separate form of disease, however, in 1851, by Senhouse Kirkes, though its mycotic nature was not discovered until comparatively recently, since Koch made his extraordinary discovery of the bacillus of tuberculosis.

I prefer the term mycotic endocarditis to any of the somewhat numerous others suggested, including ulcerative endocarditis, malignant endocarditis, infectious and diphtheric endocarditis, because it indicates the origin and nature of the disease better than any other, though the term malignant endocarditis, preferred by many, certainly gives a more accurate picture of the chief clinical features of the disease.

In the present instance the diagnosis is comparatively easy, because we have the history of a previous chronic endocarditis; and given such an endocarditis, with the supervention of the symptoms described and the elimination of a possible malarial cause, the diagnosis is at once apparent. The aid furnished by the preëxisting cardiac disease is not, however, always present. In a few instances the disease originates *de novo*, without the discovery of a previous cause or concurrent disease, constituting thus a true primary mycotic endocarditis. Fortunately, in the majority of cases, there is a concurrent infectious disease, which probably furnishes the infecting bacterium. Of such diseases pneumonia is the most frequent. The disease occurs also in association with gonorrhea, rheumatism, pleurisy, puerperal fever, bone-necrosis, and septicemia from any cause. More rarely it has been found in connection with meningitis, small-pox, diphtheria, scarlet fever, tuberculosis, and dysentery. The micro-organism that is directly responsible for the disease is usually that of the infectious disease responsible for the endocarditis. Most frequently, perhaps, it is the lancet-shaped bacillus of pneumonia, after this pus-organisms, the streptococcus and staphylococcus.

As to the acute cardiac lesions associated we find, in addition to the old sclerosis, three sets—vegetative, ulcerative, and suppurative. The vegetative are for the most part made up of closely packed spherical micrococci more or less commingled with small fibrin-masses. The vegetations vary in size from that of a pin's head to a pea, and are reddish-yellow in color. The seat of this vegetation becomes rapidly necrotic and breaks down into an ulcer which may perforate the valve, with or without previous protrusion, constituting in the latter event the so-called valvular aneurysm. More rarely minute foci of pus are found in the deeper tissues of the valve-leaflets. The invasion is, however, not always confined to the valves of the heart, but may extend to the mural endocardium. Of the valves the mitral is most frequently involved; next the aortic; next both mitral and aortic jointly; next the lining of the heart-wall; next the tricuspid, and last the pulmonary valve. In a few instances the right heart alone is invaded. Other morbid changes include the lesions of the concurrent affection and the phenomena of embolism due to lodgment of fragments of vegetation. The resultant when complete is a metastatic abscess, though the earlier stages of red infarction may also be present. On the other hand, embolism is not invariable. It may be totally absent.

In this particular case we have had, however, a number of embolic lodgments, the first being that noted as occurring before admission and before the endocarditis had become malignant. You will remember that a part of the symptomatology narrated was, in addition to the left hemiplegia, a decided increase in the tendon-reflexes. We may pause for a moment, with advantage, to consider the explanation of this interesting phenomenon. The lodgment referred to evidently took place in the cortical motor area, in which is also seated an inhibitory control over the tendon and muscle reflexes, by means of which they are kept within bounds. The effect of the lesion was to destroy this inhibition, and the reins were, so to speak, let loose upon the reflexes, which became unmanageable and were increased to such degree that the slightest tap on the radius or ulna caused a very prompt flexion of the forearm on the arm or the periosteal reflex.

Of the embolisms which occurred subsequently to the invasion of the malignant form of endocarditis upon the simple form, the first we could definitely locate occurred in the spleen, resulting in the enlargement and tenderness already noted as present. A day or two later the event of a sharp abdominal pain, followed very closely by diarrhea, led us to believe that there was embolism of one of the intestinal bloodvessels. Next came the embolism of the kidney, as the result of which there appeared in the urine an increased amount of albumin, blood-corpuscles, and blood-casts, without, however, pain, which sometimes occurs in connection with renal embolism. Then we had the second cerebral embolism, slight in degree and temporary in the duration of its effects, occurring on the morning of the 14th; and finally the cutaneous embolisms just described as having happened some time during the night of the 14th and 15th.

In addition to these seats of embolic lodgment we may have also embolism and hemorrhagic infarct occurring in the lungs from emboli starting in the right heart, while those starting from the left heart are found in the systemic organs. The number of embolisms varies greatly in these cases. It has been already said that they may be altogether absent, while they may be counted by hundreds, in which event they are, of course, very small.

It is not often that we have so strikingly present the symptoms of ulcerative endocarditis shown by this case, and which make the diagnosis in this instance comparatively easy. It will be remembered that we had here a primary chronic valvular heart-disease, which at once suggests the invasion of the malignant form, if the chill and fever so irregular in type are added. Given, however, a pneumonia, a pleurisy, the puerperal process, and the supervention of a similar set of symptoms, this form of heart-disease should be immediately thought of and the heart carefully examined for the auscultatory signs of endocarditis. In the primary forms, though rare, we have not even the presence of one of the diseases named to suggest the occurrence of ulcerative endocarditis. Here the resemblance to intermittent fever is even more close, but a careful study of the temperature-chart from day to day, and above all the utter failure of the antiperiodic remedy to produce any effect, will in a short time show that the malarial disease is not present. I do not doubt, however, that very many times has the malady under consideration been mistaken for intermittent fever, and with reason, for many a case of irregular quotidian and tertian fever presents symptoms not more diagnostic. It always greatly aids the diagnosis when to these are added other symptoms suggesting the embolism which so frequently occurs. And the occurrence of a hemiplegia or pain in the region of the spleen, with increased dulness on percussion, or pain in the region of the kidney, with hematuria, or a sudden blotch in the skin of the kind described, is of inestimable importance in aiding the diagnosis. More rare symptoms of similar origin are impaired vision from retinal hemorrhage, parotiditis, and abscess of the parotid gland.

A further study of the symptoms of malignant endocarditis permits their classification into four groups, known as the *septic*, the *typhoid*, the *cardiac*, and the *cerebral*.

The *septic* type occurs in connection with septic processes, an external wound, the puerperal process, or acute bone-disease with necrosis. The symptoms added are rigors, irregular fevers, and sweats. Yet these are only the symptoms characteristic of pyemia. In fact, it is a pyemia; and the term arterial pyemia, suggested by Wilkes, is a good one, because the pyemic abscesses are the result of embolism, whose emboli start in the left heart and lodge in the arteries. The presence of the endocarditis constitutes a distinct feature of the disease, but its symptoms may be masked, though careful examination of the heart will generally furnish its signs. The resemblance to intermittent fever here exists also, and a quotidian or double tertian type may be simulated, or the symptoms may develop in persons with chronic heart-disease without external symptoms.

The symptoms of the *typhoid* type are even more characteristic. There are here too the same prostration, irregular temperature, and sweating; but rigors are less frequent, while the onset is more gradual. There are delirium, drowsiness, often looseness of the bowels, with distention of the abdomen and tenderness in the right iliac region, to which also a rash may be added, which, though not identical with that of typhoid fever, is nevertheless similar to it. The tongue is dry and brown, and sordes collects about the teeth. The temperature is remittent, like that of typhoid, reaching 103° and 104° F., and even higher. Here again the heart-symptoms may be overlooked.

In the *cardiac* type are included those cases in which there has been chronic valvular disease, on which has supervened fever, with rigors and sweats, and the symptoms of embolism described as having occurred in the present case.

The symptoms are not always as pointed as detailed, while they may include others not mentioned. The fever may not be as high, but it is always present; again, it may not be remittent, but continuous. There may be jaundice, precordial oppression, shortness of breath, while heart-symptoms may be altogether absent, when it is almost impossible to make the diagnosis or to distinguish the disease from a septic fever of the ordinary kind. The pulse and respirations are invariably accelerated. Albuminuria and casts occur in all forms, either as the result of acute nephritis or of renal embolism.

If there is anything peculiar about the physical signs, it is their want of definiteness. When murmurs are present it is often difficult to locate or time them precisely. They often vary from day to day. They may occur at both base and apex, and with reason, for both sets of valves may be and often are involved. The super-addition of pericarditis adds a further source of confusion in the friction-sound superadded.

Still another group is the *cerebral*, in which the symptoms simulate meningitis, basilar or cerebro-spinal, and acute delirium may be present, in marked contrast to the mental state of our patient, whose mind is very clear.

As to complications, these are mainly the original cardiac disease and the diseases that most frequently cause the mycotic inflammation. Pericarditis and pleurisy are frequent complications in the strict sense of the term. So is meningitis. Acute nephritis, the result of the poison of the microbe circulating in the blood and independent of embolism may be present, with all the characteristic symptoms, blood-casts, free blood-corpuscles, and pronounced albuminuria. Gastro-intestinal derangements are sometimes conspicuous when not of embolic origin. Diarrhea was especially troublesome in our patient.

The *diagnosis* is easy only in the cardiac group. A few days' study of the temperature, with its extreme fluctuations, the rigors and supervening sweats, should at once lead to suspicion, and these, if continued, mean only one thing. The other forms are not so easily recognized; but if one would always remember the possibility of the occurrence of malignant endocarditis in connection with the diseases named, it would be less frequently overlooked. The presence of concurrent disease should guard us against the conclusion that there is typhoid or rheumatic fever. Septic fever is essentially the same in all cases, the heart-symptoms adding the only peculiarity. In true typhoid fever there is always splenic enlargement and often parotiditis, so that the presence of these symptoms naturally suggests that disease, and an erroneous diagnosis is not inexcusable. It is said that splenic enlargement is not so marked as in typhoid fever, but in my experience it is quite as conspicuous, but there is commonly more tenderness in mycotic endocarditis. Rheumatic fever often more closely resembles malignant endocarditis, with its high irregular fever and copious sweats, while confusion is further contributed to by the fact that endocarditis is one of rheumatism's most frequent complications, the mycotic form being a possible though a rare instance. The joint-symptoms of rheumatism are, however, more conspicuous at an early stage of the disease, and recurring rigors are not usual in rheumatism; but there is no enlargement of the spleen, nor are there symptoms ascribable to embolism unless secondary to endocarditis. The ultimate failure of remedies in the malignant form settles the question. The essential identity of ordinary pyemia and malignant endocarditis has been mentioned, and only the endocarditis and its consequences, which make it different from ordinary septic fever, can suggest the true nature of the sepsis.

The prognosis is always unfavorable, though the disease may be prolonged for many weeks and even months. Usually, however, five or six cover its course, while some cases are of shorter duration. Eberth reports one fatal in two days.

Treatment unfortunately avails little. The patient should be kept at rest. Remedies should be restorative and supporting—quinin, stimulants, digitalis. Nourishing food is indicated. The high temperature may be treated by sponging or by an ice-cap or by Leiter's coils applied to the thorax or abdomen; but it is seldom of so long duration as to require special treatment.

AUTOPSY AND COMMENTS THEREON.

A few days after the foregoing lecture was delivered the patient died, and an autopsy was secured. The diagnosis was fully confirmed in the finding of a greatly hypertrophied heart, whose valves, both aortic and mitral, were richly beset with characteristic vegetations, the aortic lunulæ being further eroded to nearly half their extent. The kidney and spleen, on the other hand, presented lesions which, while not identical with those foretold in the lecture, were still of a kind consistent with the primary conditions and most interesting and instructive. The kidneys, instead of being the seat of embolism as expected, because of the sudden hematuria, blood-casts, and increased albuminuria, were found to be the seat of a typical acute hemorrhagic nephritis, a frequent complication and the direct result of the action of the infectious organisms. The spleen contained four hemorrhagic infarcts; yet these were all old, being opaque, white, and much reduced in size, and could not, therefore, have been responsible for the acute enlargement of the spleen recognized before death and found at autopsy. The organ weighed 480 grams and presented on section an intensely bright-red surface on which stood out with distinctness the white dot-like Malpighian bodies, easily visible to the naked eye. The liver was much enlarged, weighing 1700 grams. The brain was not examined.

The Treatment of Diphtheria with the Antitoxin.—Soltmann (*Deutsche medicinische Wochenschrift*, 1895, No. 4, p. 53) reports that from April 1st to December 31st, 193 cases of diphtheria were treated in the Children's Hospital in Leipsic, with 50 deaths, a mortality of 27½ per cent. During the last five months of this period, when most of the children were treated with the antitoxic serum, there were 22 deaths among 122, a mortality of 18 per cent. Among those treated with the serum the mortality was 14.6 per cent., while among those treated with other measures the mortality was 27.2 per cent. In the first four months there were 28 deaths among 71 cases, a mortality of 39.8 per cent.

CLINICAL MEMORANDA.

HYDRO-PYONEPHROSIS:

Successful Removal of a Forty-Pound Tumor of the Kidney.[1]

By JOSEPH TABER JOHNSON, M.D.,
OF WASHINGTON, D. C.

In the latter part of last April I was called to see Gen. John B. C., of Missouri, in consultation with Drs. Peter and Sowers. The patient was found sitting in a large easy-chair, with a pulse of 120, a temperature of 102.5°, and an enormously distended abdomen. The man was sixty-three years of age and had inherited and possessed, until five years ago, a remarkably good constitution. He had been a General in the late war and had undergone much fatigue, exposure, and privation, having slept in swamps and lived at times on the shortest rations; his health, however, had remained good. For ten years after the war he was a member of Congress, and for six years clerk of the House of Representatives. He has since and does now occupy a prominent position under the government at Washington. About five years ago he first noticed evidence of failing health. A lump appeared in his right side in the region of the liver, and was supposed up to the date of the operation to be caused by enlargement and abscess of that organ.

The lump rapidly increased in size, and the patient gradually lost flesh and strength until the date of the operation, when he could not have weighed more than eighty pounds. At no time did he suffer from pain, and only a few weeks with fever. He was supposed at one time to have malaria, at another time inflammation of the liver, and later on the diagnosis was hepatic abscess, the tumor having acquired such dimensions as to make locomotion and the performance of official duties no longer endurable. The patient was tapped on the 3d of last April, and about four gallons of ascitic-looking fluid were drawn off. The last part of the fluid was stated to be brown or more chocolate-colored, and was said to contain pus. The tumor rapidly refilled and was tapped again in two weeks, when only one gallon of purulent-looking and bad-smelling fluid was drawn off. The abdomen was not much reduced in size at the second tapping, and a third attempt was made shortly after this, but the fluid was putrid and too thick to run through the canula.

About this time the patient began having irregular chills, sweats, rapid pulse, and high fever, and it was determined, if possible, that a radical operation should be performed. At this point in his history I was requested to see the patient. His urine had been examined several times. The report had always been the same, that, whatever disease he had, his kidneys were all right, nothing ever having been found during these five years to indicate kidney-trouble. The diagnosis in my mind lay between hydatid cyst of the liver and hydronephrosis.

The patient was taken to Providence Hospital, and was operated upon on the 9th of May last. A six-inch incision was made in the median line as in ovariotomy. The cyst was found closely adherent to the abdominal wall. It was punctured at the upper angle of the wound, and between four and five gallons of most offensive gray pus drawn off. So offensive was this fluid that some of the physicians present climbed up to the upper seats of the amphitheater and opened the windows. The cyst was thoroughly washed out with an antiseptic fluid before separating the adhesions. One plan had been to empty and disinfect the cyst and pack it full of iodoform-gauze. This was found to be impracticable, as it would have taken half a bushel to fill it. The only course left was to enlarge the incision and to enucleate the sac. When the adhesions had been sufficiently separated to pass the hand up to the liver, this organ was found to be perfectly healthy and in no way connected with the tumor. The origin of the growth was then traced back to the right kidney. The only choice left was a complete nephrectomy, which was accordingly done. Numerous adhesions were tied for fear of hemorrhage. The vessels in the pedicle were tied separately. The ureter was traced down very near the bladder and tied, cut, and dropped. The entire tumor, fluid and solid, weighed about fifty pounds. The abdominal cavity was then washed out and closed up in the usual way. A glass drainage-tube was left in. This was removed in twenty-four hours. The patient had a smooth and uneventful recovery. A curious feature about the case is the large amount of water from the remaining kidney. Thus on the first day were passed twenty-four ounces, on the third and fourth sixty-four ounces, and on the sixth day six quarts. Soon after this the quantity settled down to the normal, and has since remained so.

I saw the patient last week, and he reports himself as feeling better than he has for ten years. He has gained over sixty pounds in weight and is attending to his business without any difficulty.

There are several points of interest in this case, to wit: failure of a number of good men to make a diagnosis, though the patient was under observation for nearly five years; failure of repeated examinations of the urine to detect the slightest evidence of disease of the kidney (the only explanation that I have to suggest is that the disease at the time of analysis and subsequently had so destroyed the function of the kidney as to prevent the escape of any urine at all, and that the specimens examined all came from the other organ, which fortunately was healthy); failure of such large quantities of foul-smelling pus to produce more sepsis; absence all through the history of pain and fever; the median-line incision, the separate ligation of the renal vessels, and the ligation and dropping of the ureter.

I am aware that the lumbar incision is preferred by nearly all nephrectomists, and that they often bring out the cut end of the ureter and fasten it in the abdominal wound. While the lumbar incision may be best in small tumors and otherwise diseased kidneys, it certainly could not have succeeded in a case of the magnitude of the one just reported, not only on account of the great size of the tumor, but also because of its being so extensively adherent to the omentum and abdominal wall. The colon had to be carefully separated from the anterior surface of the tumor.

While this was a very large hydronephrosis, which after tapping became a pyonephrosis, it was not so large by twenty-five pounds as one I removed for Dr. Bedford Brown in Alexandria, Va., which was mistaken by us all for an ovarian tumor. In that case the tumor weighed seventy-four pounds.

CASE OF SUPRA-SPINOUS DISLOCATION OF THE RIGHT SHOULDER, PRESUMABLY OCCURRING AT BIRTH.

By BERTHA LEWIS, M.D.,
INSTRUCTOR IN ORTHOPEDIC DEPARTMENT OF THE PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE; CLINICIAN IN CHARGE OF ORTHOPEDIC DEPARTMENT OF THE WOMAN'S HOSPITAL.

In August, 1894, Joseph S., eleven months old, was brought to the Neurological Department of the Philadelphia Polyclinic, as the mother had been told her baby's right arm was paralyzed. A critical examination by Dr. J. W. McConnell and myself revealed the fact that there was no loss of power in any of the muscles of hand or forearm, but that there was fixation at the shoulder. The case was at once referred to the orthopedic department of the same hospital, when I again saw the case in conjunction with Dr. J. Torrance Rugh. The mother gave the following history:

The child was born September 23, 1893, the labor being long and difficult; the forceps was used to deliver the head of the child; delivery of the shoulders was delayed and difficult, force being again required, but the history is not clear whether the fingers or a hook was applied. When the child was born it was too badly bruised to admit of handling, and had to be rolled in cotton. On the second day the nurse called the doctor's attention to the limp condition of the right arm, but no attention was given to it, the mother says, further than to assure the family that "the arm would be all right in a short time, that it was a little injured from pressure."

Nothing was done until the end of the third week, at which time the family physician returned to the city, and the mother called his attention to the arm. He examined it and applied a bandage, placing the arm approximately in the Velpeau position. This treatment was continued for two months, at the end of which time the condition of the arm was not improved. The mother's anxiety was not allayed by the assurance that the arm would come right in time if she did nothing, and that only a nerve had been injured. The mistrust in this wise (?) counsel brought her to the neurological department as already stated.

Examination in the orthopedic department showed fixation at the right shoulder, the head of the humerus protruding above the spine of the scapula posterior to the acromion process and being firmly fixed in this position. The head and neck of the humerus could be clearly outlined, the muscles being very flaccid from lack of use. The marked anterior rotation of the humerus in its long axis produced an exaggerated pronation of the forearm and hand.

The child was put under ether for a more complete diagnosis and the reduction of the deformity, because of the limited motion and the long duration of the deformity. Firm fibrous ankylosis was anticipated, but when complete relaxation was obtained, and the scapula fixed, extension applied to the arm caused the head of the humerus to slip easily into the glenoid cavity. No adhesions had formed; rotation, adduction, abduction, all movements were free. Then came the problem of maintaining the correction, as we had to deal with abnormally contracted muscles and ligaments posteriorly, and the reverse or greatly relaxed muscles and ligaments anteriorly.

The unique method was suggested by Dr. Rugh, of applying a plaster-of-Paris bandage with the arm in position in which the deformity had been reduced—namely, that of extension laterally, the arm and forearm on a plane with the trunk and on a level with the shoulder. This was done; pressure was made in the plaster-of-Paris, while soft, at a point posterior to the acromion and below the spine of the scapula. The plaster-of-Paris bandage was carried to the wrist. This dressing was removed on the eighth day, when it was found that the head of the humerus had slipped a little posteriorly. The arm was then slightly over-extended posteriorly to the plane of the trunk, and a second plaster-of-Paris bandage was applied. In this, as in the first application, the bandage was carried around the trunk, over the shoulder, and down to the lower angle of the scapula, over the right arm to the wrist. The child was restless for the first two nights, but was quiet and comfortable afterward.

This treatment was continued for eight weeks, when the bandage was finally removed, and the arm maintained nearly a normal position. Owing to the long period of inactivity, for the part had never had any normal period, there is slight stiffness at the shoulder. Supination is difficult, and pronation is greatly exaggerated. Movements, with massage and electricity, have been used in the subsequent treatment. Passive movements in all normal directions, and massage of the muscles of the upper arm and shoulder, have been practised on each visit of the child to our clinic, and the mother has been instructed to practise massage daily.

This has been a very unusual as well as an interesting and instructive case. I have been unable to find any report of a case of supra-spinous dislocation occurring at birth. Most authorities claim that the supposed cases of dislocation have been fractures or separations of the epiphyses from the shaft of the humerus, but we are certain that we had a case of supra-spinous dislocation of the right humerus, as the head of the bone was distinctly outlined above the spine of the scapula, and had it been a fracture or an epiphyseal separation, reduction could not have been accomplished so easily and completely.

CEREBRAL FUNGUS—EXCISION AND CAUTERIZATION OF PEDICLE—RECOVERY.

By HENRY M. KELLER, M.D.,
OF HAZLETON, PA.;
SURGEON-IN-CHIEF AND SUPERINTENDENT OF THE HOSPITAL FOR INJURED PERSONS OF THE MIDDLE COAL-FIELDS OF PENNSYLVANIA.

Andrew W., aged twenty-eight years, was admitted to the hospital October 2, 1893, with a compound fracture of the frontal bone, immediately over the left frontal eminence. One week before admission he had been struck on the head with a beer-bottle. The physician in attendance had treated it as an open wound; no attempt had been made to elevate the depressed bone, and the wound was packed with lint. On admission the patient was perfectly conscious, the pulse 80 and full, the temperature 98.4°. An examination revealed a depressed fracture three-and-a-half inches long, by one inch wide; the wound was infected. The man was immediately prepared for operation, the trephine applied, and a large section of depressed bone removed. The dura was found torn and the brain-substance lacerated. Some lacerated brain-tissue was removed, the wound thoroughly cleansed and catgut drainage inserted. The patient reacted from the operation, and the following three days the temperature-range was between 98° and 100.4°. On the third day the dressings were removed and a small amount of pus was found. On the seventh day a rapidly growing fungus had torn out several stitches. The remaining stitches were now removed in order better to cleanse the pus-covered fungus. The growth had by this time attained the size of a small hen's egg. Compression by means of gauze-pledgets was now employed, and was kept up for twelve days, with no diminution in the size of fungus. The man became dull, had a vacant expression, would not talk to his friends, and on several occasions failed to recognize his brother. The temperature never rose above 100°, and the pulse was slow. Having failed to accomplish anything by compression, on October 21st, or the nineteenth day after his admission, he was placed under ether and the growth was cut off on a level with the skull. The pedicle, which was quite broad, owing to the large size of the fracture and loss of brain-substance, was cauterized with a Paquelin cautery; the wound was thoroughly cleansed and packed with iodoform-gauze and dressings were applied. After operation the temperature fell from 99.6° to 98°. The mental condition remained about the same for a period of a week or ten days, and then began to improve. The wound was repacked every second day until the discharge ceased; the edges of the scalp were then freshened and brought together, several strands of catgut being still used for drainage. A slow recovery followed, and on December 18th the man was discharged from the hospital, the wound having healed entirely and the mind being perfectly clear. This case is presented as being of interest merely from the fact that a complete cure was effected by excision of the growth and cauterizing of its pedicle.

PATHOLOGIC NOTE.

SOME NOTES ON THE USE OF FORMALIN AS A MORDANT IN ANILIN-STAINING.

BY A. P. OHLMACHER, M.D.,
OF CLEVELAND, OHIO.

THE idea of using formalin as a mordant in anilin-staining occurred to me quite by accident. Some tuberculous sputum for use in the laboratory-classes was procured two or three days before the exercise, and, with a view of preserving it and of destroying the vitality of the tubercle-bacilli, a plug of cotton was impregnated with a few drops of formalin and secured in the top of the tall, wide-mouthed, screw-cap jar containing the sputum. In this way the vapor of the formalin alone could penetrate the sputum. When this sputum was distributed for class use it was not visibly altered in appearance, although it smelled strongly of formalin. The cover-glass preparations, made in the usual way, were stained with Ziehl's carbol-fuchsin, and decolorized with a 25 per cent. sulphuric-acid solution containing 1 per cent. of methylene-blue (Gabbet's method). I was surprised to find, in the hands of all the members of the class, that the bleaching and counter-staining solution had utterly failed to decolorize the preparations in a few seconds, as is usually the case. A longer application of the decolorizing solution was advised, with no benefit. Thinking the decolorizing solution at fault, a fresh solution was prepared and distributed. Still the red color of the fuchsin persisted, even though the powerful decolorizing solution was allowed to remain five minutes in contact with the preparation. The preparations were mounted in despair and examined. It was found that the stain was retained by the pus-corpuscles, both in their nuclei and protoplasm, and by the tubercle-bacilli. The other bacteria and the mucus were stained with the blue. On the occasion of this laboratory-exercise the preliminary exposure of the sputum to formalin-vapor was quite forgotten, and I could not account for the strange behavior of the staining experiments. Pondering on the subject, the idea of the formalin being responsible for the trouble occurred, and with it the suggestion that, if the formalin was responsible, it was due to a very powerful mordanting effect of its vapor. Two samples of tuberculous sputum were now examined, one previously exposed to the vapor of formalin for twenty-four hours, the other not so treated. The same staining method as previously outlined was employed, and the formalin-sputum repeated in every way the peculiarity of the class-room sample, while the control-sample stained and decolorized in the usual manner. Thus the idea of using formalin as a mordant in anilin-staining was suggested, and experiments were at once set afoot. As my routine work at this time has to do with bacteria, most of my experiments with formalin have been made on this class of objects.

Formalin may be employed in bacteria-staining preceding one of the ordinary dyeing solutions, as, for example, carbol-fuchsin, anilin-water gentian-violet, and aqueous methyl-violet and aqueous methylene-blue. For this purpose a 2 per cent. or 4 per cent. aqueous solution of formalin is used. The fixed film of a cover-glass preparation is treated for one minute with the formalin-solution, washed with water, and stained one minute *in the cold*. Conducted in this manner the staining is much more intense than when the dyes are employed without the mordant; in fact, it is possible to stain in the cold with the aid of formalin and produce better effects than when heat is employed in the old way. The advantage of this feature is evident, for no one can deny that the heat employed in our routine bacteria-staining is a bad element.

Aside from its use as a mordant preceding other staining solutions, formalin may be employed as the base for staining solutions, just as anilin, carbolic acid, etc., are employed in the standard formulæ.

A formalin-fuchsin that appears to keep well may be made by adding 1 gram of fuchsin dissolved in 10 c.c. of absolute alcohol (*Fuchsin für Bacillenfärbung*, Grübler) to 100 c.c. of a 4 per cent. aqueous formalin-solution. This solution stains energetically in the cold.

Formalin-gentian-violet may be made by adding to a 4 per cent. aqueous formalin-solution a saturated alcoholic solution of gentian-violet (Grübler), in the same proportion as employed in making the Koch-Ehrlich anilin-water solution of this dye.

A formalin-methyl-violet is made like the gentian-violet solution, except that a saturated alcoholic solution of methyl-violet (*5* B., Grübler) is used.

Formalin-methylene-blue can be made by dissolving 1 gram of methylene-blue (*Methylen-blau nach Ehrlich*, Grübler) in 100 c.c. of a 4 per cent. aqueous formalin-solution. All of these solutions appear to be as permanent as the corresponding mixtures of other formulæ.

All of these mixtures are powerful stains for bacteria, even when employed without heat. It has not been possible as yet to devise specific stains for certain bacteria with the aid of formalin-solutions; but much may doubtless be accomplished in this direction. The few experiments that I have made in flagella-staining with formalin have been negative, though there is reason to hope that on account of its powerful mordanting action this agent may, with certain procedures, become a valuable aid in staining the motile appendages of bacteria. In spore-staining, also, the field for the employment of formalin is inviting.

In tissue-staining, for general or special purposes, the formalin-anilin solutions promise to be of great utility. The formalin-solutions of fuchsin, gentian-violet, methyl-violet, and methylene-blue may all be used in tissue-staining. Most of my experiments in tissue-staining have been confined to the formalin-methylene-blue solution (formula already given). Sections of anthrax rabbit tissue fixed in absolute alcohol, Carnoy's chloroform-acetic-alcohol, or Hermann's solution, and affixed to the slide by the water-albumin method, were stained half a minute with the formalin-blue, washed in absolute alcohol, cleared in xylol, and mounted in xylol-balsam. On account of the mordanting effect of the formalin, the methylene-blue remains in the tissue with great persistency, and there is no danger of washing it out with absolute alcohol, as is commonly the fault. These preparations exhibit a beautiful dark-blue and precise nuclear staining; the bacilli stand out sharply with a stain so intense as to appear almost black, and red blood-cells, when present, stain a curious yellowish hue. Karyokinetic nuclear figures in the splenic tissue were stained very prettily and sharply with the blue. This staining succeeded with the tissue fixed in the three different fixing solutions.

A curious effect was obtained when safranin (*O wasserlôslich*, Grübler) was dissolved to saturation (in the cold) in a 4 per cent. aqueous formalin-solution. The anilin-water solution of this dye is a powerful and precise nuclear stain when used by the indirect method of anilin-staining; but the formalin-solution proved to be a *plasmatic* stain, comporting itself in all essential particulars like eosin. A section of the kidney of the anthrax-rabbit, stained first with formalin-methylene-blue, and then with the formalin-safranin, gave a beautiful double stain. The protoplasm of the renal epithelium stained light-red; the chromatin nuclear framework a reddish-blue; the nucleoli a deep-blue; and the bacilli, in the glomeruli, were rendered very prominent by their heavy stain.

In connection with methylene-blue staining it is suggested to those particularly engaged in neurologic work that formalin may be found to be a mordant and preservative that will prove of great aid in fixing this ideal stain in the nervous elements, and in preserving these specimens.

From these observations, based on introductory experiments, it is evident that formalin promises to be a very valuable and widely useful agent in microtomy. A great many experiments with this new mordant will naturally suggest themselves to specialists in the various departments of microscopic laboratory-work.

MEDICAL PROGRESS.

Castration for Prostatic Hypertrophy.—Swain (*British Medical Journal*, No. 1775, p. 12) has reported the case of a man, seventy-three years old, who for five years had suffered from difficulty in passing urine. During the greater part of this time he was compelled to use a catheter to empty the bladder. On several occasions he had received treatment for retention, and a number of times the urine had contained blood. Six weeks before coming under observation the man had suffered a "stroke," and subsequently the bladder-symptoms had been much aggravated. He was compelled to rise four times during the night to pass urine. There was considerable pain in the bladder, and the use of the catheter was constantly necessary.

The man came under observation for the relief of retention. A soft catheter was introduced, and the urine, which was decomposing and contained a large quantity of blood, was withdrawn. By rectal examination the prostate was found to be very hard and prominent, and about as large as an orange. It was impossible to touch the top of it with the finger. Subsequently the catheter could not be introduced, and the bladder was aspirated above the pubes. On the third day a metallic prostatic catheter was passed, which traversed the urethra for nine-and-a-half inches before the urine began to flow. The considerable depression of the handle that was necessary suggested that the middle lobe, as well as the lateral lobes, was much enlarged. For about ten days the bladder was irrigated night and morning with boric-acid solution, and, although the urine contained very little blood and was less fetid, the prostate did not diminish in size and the patient was gradually getting worse.

The kidneys were presumably healthy, as the total amount of urine excreted daily was about normal. Double castration was proposed and accepted. In consequence of the decomposition of the urine it was necessary to continue the irrigation of the bladder for three weeks after the operation, but on the seventh day the patient passed a small quantity of urine of his own accord, and this gradually increased in amount, so that when the washing out of the bladder was stopped he passed all his urine naturally. Coincidentally with this, his general condition improved and the prostate gradually became smaller. There was a perceptible diminution in the size of the gland at the end of the first week after the operation; but in the third, fourth, and fifth weeks the increasing atrophy appeared to progress more rapidly. In three weeks after the operation the patient began to get about, and in five weeks he was dismissed.

At this time his general condition had greatly improved. His urine was normal; he sometimes passed half a pint at a time, but he could not hold his water for more than four or five hours in the daytime. There was no residual urine in the bladder; the prostate was comparatively soft and about the size of a large horse-chestnut. If a catheter was introduced, it passed easily, and urine began to flow along it when a distance of eight inches from the orifice of the urethra had been reached and without any more depression of the handle than is usual. Thirteen weeks after the operation the patient had been able for eight weeks to dispense with the use of the catheter, and was not compelled to arise at night. He was free from all difficulty in emptying his bladder, and the urine was normal in appearance and odor. On rectal examination the prostate was found to be rather smaller and firmer than at the previous examination.

RICKETTS (*Medical Fortnightly*, vol. vii, No. 2, p. 33) has reported the case of a man, seventy-four years old, who was much distressed by greatly increased frequency of micturition, associated with great pain and disturbance of sleep. Attempts to introduce a catheter had been unsuccessful. After relief of the immediate symptoms, and keeping the patient under observation for ten days, bilateral orchectomy was performed. The patient bore the operation well, and suffered no inconvenience or pain thereafter. On the second day after the operation urination was easier and sleep was better. The patient was dismissed on the sixth day much improved.

Hypertrophic Macrochiria of the Right Arm.—CHASSIOTIS (*Monatshefte für Praktische Dermatologie*, vol. xix, No. 12, p. 674) has reported the case of a man, twenty-five years old, who came under observation on account of a deformity of the right upper extremity which had been present from birth. He related that he had been able to use the member until twenty years of age, particularly the fourth and the little fingers, which, though apparently atrophic, were of physiologic size and form. During an imprisonment for some transgression at this time he observed the right hand to become swollen, and from fear of an unfavorable result asked to have the member amputated. The right upper extremity had become so enlarged that, to maintain his equilibrium in standing, the patient was compelled to incline his head toward the left side.

The enlargement began anteriorly at the outer margin of the pectoralis major, above the acromion, posteriorly at the upper extremity of the outer margin of the axilla, and appeared to involve, down to the elbow-joint, only the anterior and external aspects. The tissues of the part were flabby. Sensibility was preserved. From the elbow-joint to the root of the hand the enlargement presented a certain degree of induration, though upon the inner side the muscles and bones were palpable. The hand retained somewhat the form of a normal member; the thumb and the index and ring fingers were enormously enlarged, and sensibility was lost upon the palmar aspect of their third phalanges. The skin of the palmar surface was hard and presented a peculiar rose tint. Upon examination of the amputated member the increase seemed to involve all of the constituent structures.

Removal of Partially Encysted Dumb-bell-shaped Calculus by Lithotomy.—At a recent meeting of the Philadelphia Academy of Surgery Dr. H. R. WHARTON reported the case of a child, five or six years of age, in which on examination a stone was found in the bladder. Some hesitation was for a time felt as to what operation should be performed. Litholapaxy was decided upon, but when the child was etherized there was felt on rectal examination a prolongation of the bladder into the rectum containing the stone. Lateral lithotomy was then undertaken, and after exposing the stone and attempting to grasp it, it was found impossible to remove it, as the posterior portion was thoroughly surrounded by the wall of the bladder. The stone was dissected out with the finger without breaking it. The patient did perfectly well after the operation.

THERAPEUTIC NOTES.

Sodium Fluorid for Tuberculosis in Infants.—As the result of a clinical study BOURGOIS (*Bulletin de l'Académie Royale de Médecine de Belgique*, 1894, No. 11, p. 874) arrives at the conclusion that sodium fluorid exercises a useful influence upon infants either predisposed to tuberculosis or already tuberculous. The good results obtained were permanent, and in several cases recovery had been maintained for several years. The doses employed varied from .0001 g. (gr. $\frac{1}{7}$) to .005 g. (gr. $\frac{3}{4}$) daily in fractional parts, and were proportionate to the chronicity of the disease. When the good effects of the treatment become apparent the dose may be reduced, and finally omitted, unless the amelioration does not continue, when the original dose should be resumed. No disadvantage was observed from the use of the drug, which appeared perfectly inoffensive, and was well borne.

The Treatment of Obstruction of the Bowel by Electricity.—ALTHAUS (*British Medical Journal*, No. 1778, p. 188) has reported the case of a man, fifty-four years old, who for three months had suffered with obstinate constipation. At the time of coming under observation the bowels had not been moved for ten days, and the abdomen was distended and tender. The appetite was lost, and a condition of collapse existed, with sunken face, and a small, feeble pulse. The introduction of a long tube proved unavailing, and electric treatment was resorted to. An insulated sound, with a free metallic end, was introduced into the rectum, and a moistened conductor applied to the abdominal parietes, chiefly in the region of the sigmoid flexure. Through this circuit a primary faradic current was passed, and its force gradually increased until the patient experienced a decided feeling of vibration in the bowel. In the course of the day a copious intestinal evacuation ensued, with wonderful relief to all of the symptoms. During the next two days the bowels acted ten times, and in the course of a week the patient appeared to be quite well. A second case, in a woman fifty-seven years old, is cited in which a like result was obtained from similar treatment.

SATURDAY, FEBRUARY 16, 1895.

THE BRITISH TITLE "DOCTOR."

In Great Britain it is notorious that the people are somewhat of precisians in their methods of styling one another. There are definite laws regulating the procedure in addressing all the different grades in the peerage and hierarchy, while the titles appropriated to the members of the branches of the public service are very exact. It is, therefore, a little bewildering to our notions of uniformity to find that the rules according to which it is correct or incorrect to address a medical man as "Doctor" are by no means clear. We are talking of professional and scientific society, of course, and not of society at large, which, correctly or incorrectly, will always call the medical man "Dr.," without any intention to confer upon him an unearned university degree, but solely as a ready method of calling the attention of the company to his status or of singling him out for identification. And before laying down exactly who is and who is not in England entitled to prefix "Dr." to his name, we cannot refrain from pointing out the awkwardness of the fact that all medical men in the United Kingdom are not allowed by custom to call themselves "Dr." under all circumstances. It is inconvenient when a desire to be accurate entails the necessity of always alluding to any one member of the medical profession as a physician or surgeon, instead of being able to lump his titles under the generic term "Dr.," for the word "practitioner" does not cover the whole of the profession, but is restricted in its use for the designation of those in general practice in contradistinction to those whose work is purely consultant.

In Great Britain the only persons in the medical profession with a clear right to prefix "Dr." to their names are those holding the diploma of Doctor of Medicine in the Universities of England, Ireland, and Scotland; and these gentlemen for various reasons form but a small percentage of an overcrowded profession. The Universities of England, in order of seniority, which can confer the degree of Doctor of Medicine upon their medical graduates are Oxford, Cambridge, Durham, London, and Victoria; those of Ireland are Dublin and the Royal University; and those of Scotland are Edinburgh, St. Andrew's, Glasgow, and Aberdeen. The possessors of the degree of Doctor of Medicine obtained at any of these eleven universities have a clear and indisputable right to be styled "Dr.," and although, as we shall see, there are numerous circumstances that entitle others to use the same style, they must be held to do so rather by concessions of courtesy than by right.

The value of these eleven different diplomas, viewed from the point of the severity of the tests to which their holders have been exposed, varies infinitely; but indisputably the London degree is the hardest to acquire. Again, education at either of the two preëminently ancient seats of learning carries with it a certain social prestige. For these two reasons it is to be observed that the graduates of London, Cambridge, and Oxford generally add London, Cantab., or Oxon. to the M.D. affixed to their names. It is not, however, imperative in the Doctor of Medicine to signify the body which granted him his degree. It is purely a matter of individual choice and taste. To some it would appear that, for the very reason that certain degrees are harder to obtain than others, taste should impel the holders of the more readily won titles to confess their origins; but on this point there is no law. Nor could there very well be any law, unless definite conclusions could be arrived at as to which are the readily won titles, and any attempt to formulate conclusions on this point would inevitably cause much bad feeling, while the result would be entirely unconvincing.

Doctors of Medicine in the eleven universities have a clear right, and the only quite clear and indisputable right, to be officially styled "Dr."—of course, in their character of medical men—in Great Britain. In addition to the degrees conferred by these eleven universities there are gentlemen practising the medical profession in England who possess the degree of Doctor of Medicine from recognized foreign universities. These gentlemen would be entirely correctly addressed as "Dr." in professional circles. But it must be understood that to a certain degree such a method of addressing them is an act of courtesy, as their doctorates would not appear on the register of the General Medical Council of Education and Registration, the body which in Great Britain has the control of all these matters; and were they not otherwise qualified, that is, in possession of diplomas from some of the recognized licensing bodies of the United Kingdom, they could not practise their professions, save under the disabilities entailed by being absent from the register. It is unnecessary to go into more detail. We need only say that the number of foreign universities whose degree of Doctor of Medicine is recognized in the United Kingdom as a legal registerable title, and not as an appanage to other legal registerable titles, is now very small.

We now come to a very large class whose legal and moral title to the style of "Dr." has never been questioned, but who really have no right whatever to the style, and enjoy it solely by courtesy. These are the Bachelors of Medicine of the eleven universities already enumerated. It is not difficult to understand how this has come about. In some cases there is little but a question of fees between the Doctor of Medicine and the Bachelor, and it has then been generally felt that it would be a hardship to a young man to prevent him from enjoying a title which he has mentally earned until he could pecuniarily obtain it. Again, certain of the universities impose a not too brief term of years between the granting of the M.D. degree and the earning of the M.B. degree, and this period is one in which a young man making a start ought decidedly to be allowed to avail himself of every proper opportunity of letting his professional brethren and his future clients know his status in medicine. If he has the moral right at this time to call himself "Dr.," he ought to be allowed to do so. Sometimes there is an examination to be passed; generally this takes the form of a thesis or dissertation, though at London and Cambridge Universities there is a written examination. We have now exhausted the list of persons who have a right to be called "Dr.," having attempted to divide them into two classes, those with a legal right and those with a right by courtesy. But the broad question: Who do you call "Dr."? is not so easily settled, and any one who should be guided solely by the simple rules we have laid down would promptly find himself in error. To begin with, no pure surgeon in London, Edinburgh, Dublin, or the large provincial centers ever calls himself "Dr.," although he may have, and for that matter very generally does have, the qualifying right. In Great Britain the pure surgeon is always addressed as Mr. Thus we have Mr. Hulke, President of the Royal College of Surgeons, and M.D. Lond., but "Mr.," essentially "Mr.," as a pure consulting surgeon. In the provinces, on the other hand, it may be in quite large towns and in the centers of important populations, it will often occur that the pure surgeon, so far as his line of practice goes, will elect to be called "Dr.," if he possesses the right to the title. That is to say, he will decide upon using the exactly opposite style to that affected by his metropolitan brethren. This may be for various reasons; the usual one is that as a young man he was known as "Dr." to the countryside. It was as "Dr." that he made his reputation and obtained his practice and the position that enabled him to leave general practice, and so, when deciding to confine his work to purely operative surgery, he very naturally leans to his old title, which has hitherto stood him in good stead. As germane to this point, we may refer to the position of the obstetric physician, who is certainly and largely an abdominal surgeon. These gentlemen prefer to style themselves "Dr.," and in some cases do not possess any particularly good surgical diploma; yet much of their work is purely surgical, and could be no more dependent upon medical erudition and tact than that of the general operating surgeon. So much for persons who can be styled "Dr.," but prefer to be addressed as "Mr.," and persons whose work should really mark them off as more fitted for the purely surgical style of "Mr.," but who like to call themselves "Dr."

We now come to a class who are very usually styled "Dr.," and have, from a professional point of view, no right whatever to the title. These are the gentlemen whose professional title would only earn them the appellation of "Mr.," but who possess, in addition, a degree entitling them to style themselves Doctor of something else other than medicine. There are on the *British Register* persons holding nearly every sort of title which can give the right to assume the prefix of Doctor. There are not many Doctors of Divinity, but there is at least one, and he is a bishop. There are many more medical men in Great Britain who have the title Doctor of Laws, and now that the impulse given to State medicine is so very great there, it has become comparatively common for medical men to be called, in addition to their profession of medicine, to the bar, a proceeding that we may expect to see result in the title of Doctor of Laws being united still more frequently with medical degrees; but it must be remembered that it is not a common title, and that the bodies granting it are few in number. The recognized method in all the universities of Great Britain of honoring a man is to confer a degree upon him, and it so happens that those degrees are nearly always such as would entitle a man to style himself "Doctor," generally Doctor of Letters, and a good example of the pitfalls into which the uninstructed might fall will be furnished by mentioning one or two names. MR. HUTCHINSON, for instance, remains "MR." HUTCHINSON, because he is a pure surgeon; but he holds the degree of LL.D. Cantab., conferred upon upon him as a recognition of his distinguished services to science. He is "Dr.," undoubtedly "Dr.," and it is most undoubtedly incorrect to style him so. MR. ERNEST HART, again, as a member of the Royal College of Surgeons, is properly styled "Mr.," but he holds the honorary degree of D.C.L. Durham, in recognition of his position as editor of the official journal of the British Medical Association, which met at Newcastle (the seat of the Durham Medical School) in the year 1893. MR. HART is undoubtedly "DR." HART, but it is equally undoubtedly wrong to style him so.

It is a blessing for the precise man, the man who is uncomfortable unless he addresses people by their proper style, to remember that in Great Britain these honorary degrees are in most cases so rigidly reserved for the distinguished man that it is usual for their recipients to enjoy, either at the time of their creation or shortly afterward, some higher title in which, according to English etiquet, the minor question of "doctor" or no doctor is entirely merged. Either as knights or baronets the medical holders of honorary degrees generally settle the question of how they should be addressed by having the right to be termed Sir, as SIR JOSEPH LISTER, SIR WILLIAM JENNER, and the first and last of which, had they not been baronets, would have been good examples of individuals styled "Mr.," with the right to be styled "Dr." also.

We have now exhausted the list of those who, rightly or wrongly, by law, courtesy, or mistake, can by styled "Dr." in Great Britain *qua* medical man. We have not considered it worth while to count the names in the *British Medical Directory* with a view of ascertaining what proportion these three classes bear to the whole list; but it is safe to assert that it is a very small one. It is safe also to assert that the majority of medical men in Great Britain and Ireland have not, either by legal position or by etiquet, the right to style themselves "Dr." That they are very largely so called has nothing to do with the case. The title is purely colloquial, and used, as we have already indicated, for social purposes, to signal out its possessor and place him at once in his proper position in the company. The word "Doctor" in such a connection simply means "medical man," and is not intended to confer either a doctor's degree or university status upon its possessor. In precise writing the titles of "Dr." and "Mr." are rigidly allocated to their proper possessors, and as a rule the medical profession among themselves endeavor to observe this precision, and the man who is "Doctor" to the whole country-side will be "Mr." to his professional colleague, who knows his proper style; but even in professional circles we have noted one or two tendencies to condone a wrong use of title out of deference to the individual position of the bearer. These cases have always been when the wrongly styled man occupied some public or official position, generally some Government appointment, wherein he is in association with other officers bearing lay titles. Thus the head of a county lunatic asylum is generally granted the title of "Dr." It marks him, without further explanation being required, as the medical officer in charge of the institution, in contradistinction to the chairman, the visiting justice, the chaplain, the steward, the matron, and the rest. Similarly the prison-doctor and the medical officer of health often obtain from their professional brethren the recognition of a title which really has its origin in expediency, not law. It is probable that the element of professional jealousy may account for this anomaly. When one offering his services to a community, and possessing the legal right to call himself "Dr.," is in rivalry with two or three professional brethren not having that right, it is probable that professional jealousy—using the term without the slightest element of reproach—will urge him to enlighten the community to the fact that he is the real "Dr.," and that the others should be styled "Mr." Now, no one is in rivalry with the prison-doctor or with the medical superintendent of an asylum. They are in charge of a department, and have nothing to gain from the outside public, and there is no personal or pecuniary reason for desiring to deprive them of a title that is intended for convenience. The same attitude, we may add, was observed until a few years ago by combatant officers toward their brethren of the Army Medical Staff. But since the Army Medical Staff began seeking after strange titles their brethren, medical and military, who used to call them "Dr.," in recognition of their official position, now term them "Mr.," adding in a parenthesis that they believe that one for instance is a major-general, for how can such a cumbrous title as *Brigade-surgeon Lieutenant-colonel* ever come into familiar use?

Enough has been said to show that the simple question who should and who should not be styled "Dr." is not very simple to answer. We have only to add that those who consider it worth while to carry in their heads the foregoing rules will not go wrong; while those who do go wrong in their methods of address toward their professional brethren in the United Kingdom will find that the wrongly addressed will bear no malice, for they are daily used to it among their own folk. They are wrongly styled in all the newspapers, are habitually addressed in all law courts by titles they neither have nor aspire to, and are fortunate if their own widows and children fail to describe them wrongly upon their tombstones or memorial tablets.

EDITORIAL COMMENTS.

Total Resection of the Stomach.—We have a number of times recently had occasion to advert to the almost boundless possibilities of modern aseptic surgery. The success of the results obtained is rendered effective not only by the skill and improved technique of the surgeon, but in not a little degree by the prodigality of Nature in making such provision that when the function of one organ is for any reason diverted or lost it can be taken up by some other one or more. Thus the removal of important organs in whole or in part is rendered possible, as not being incompatible with the continuance of life. Such a condition finds its parallel in morbid anatomy, and instances are not rare in which large parts of organs and even entire viscera have been destroyed by disease without causing immediate death. It is, however, only within modern times that the more radical excisive operations have been attended with any reasonable degree of success. Thus, large portions of no less important organs than the brain, the liver, the lungs, and entire kidneys and spleens have been successfully removed. It has also been possible to prolong life and in some instances to effect a permanent cure by the excision of malignant neoplasms from the stomach and intestines. Two most remarkable cases of this category have recently been reported by LANGENBUCH (*Deutsche medicinische Wochenschrift*, 1894, No. 52, p. 968), and seem to indicate a new era in visceral surgery. In both cases resection of the stomach was performed for the relief of gastric carcinoma, with recovery in one and death in the other. In the latter the fatal issue was due to a complication only remotely connected with the operation.

The first case occurred in a woman fifty-eight years old. The stomach was found unusually small and contracted. The new growth occupied largely the posterior wall, although several small nodules were also present upon the greater curvature and had extended to the great omentum. The liver and the adjacent lymph-glands were uninvolved. The peritoneum was removed from the curvatures and a crescent-shaped section, including the nodules, was excised from the greater curvature. The stomach was now withdrawn from the abdominal cavity as far as possible and the abdominal wound closed by sutures. Gauze was carefully packed around the extremities of the stomach to prevent subsequent infection of the peritoneum. The pyloric and cardiac extremities of the stomach were now ligated through healthy tissue with tapes, and finally about seven-eighths of the stomach removed with scissors. Hemorrhage was controlled by digital compression. The circumference of the cardiac section being the larger was first somewhat reduced by suture and the free margins were united. The newly formed stomach had a capacity corresponding to the volume of a hen's egg. The pyloric portion was withdrawn as far as possible and fixed in the abdominal wound, partly by means of sutures and partly by means of iodoform-gauze. But a small amount of chloroform had been used in the anesthesia, although the operation occupied one-and-three-quarters hours.

The woman was soon able to take milk, and later the yolk of an egg with sugar, with no discomfort. In the course of the following day liquid nourishment was repeatedly given. The temperature, however, rose, and the frequency of the pulse increased. The patient appeared to be lost, although there was no evidence of peritonitis or other inflammatory process referable to the wound. The temperature and pulse, however, subsided, and the further progress of the case was entirely satisfactory. After the third day the patient was able to take meat, and when dismissed, after the lapse of several weeks, she had gained twenty-two pounds in weight, although in the interim she had been attacked with pneumonia.

The second case occurred in a woman, fifty-six years old. The stomach was so softened that despite the greatest care in its removal, rupture took place at the cardiac extremity. The small opening, however, was at once closed by suture. Resection was performed as in the preceding case, and the remains of the stomach likewise fixed extra-peritoneally. The sutures introduced failed to hold, and on the third day after the operation the dressings were found soiled with gastric contents. It soon became evident that an insufficient amount of food reached the bowel, and the patient, already greatly emaciated, grew worse and worse. An attempt was made to introduce a tube through the gastric fistula into the duodenum, but the efforts necessary, on account of the resistance at the pylorus, led to such disturbance in the relations of the parts that a local peritonitis resulted and death took place on the sixth day.

Upon post-mortem examination the inflammation was found to have been restricted to this localized area and not to have involved the peritoneum generally.

The Riverside Baths of New York.—We had the pleasure of referring a few years ago (THE MEDICAL NEWS, September 19, 1891, p. 334) to "The People's Bath," and indirectly pointing out the advantages and utility of the privilege thereby afforded, both from the moral as well as from an esthetic point of view. It was to be expected that such a praiseworthy undertaking would be imitated and extended, and the outcome of events has justified the expectation, though not, perhaps, to the degree that is desirable. At any rate the work has proved so successful in New York that it has been taken up by an organization devoted to the interests of those for whom the baths are especially intended.

The Riverside Association is a New York institution, whose object is to aid and elevate workingmen and encourage self-dependence among them. Recognizing that the essential principle of all sanitation is cleanliness, the association has taken practical steps to enforce this principle. Among the useful measures directed toward this end is the establishment of public baths accessible to workmen and their families for a nominal pecuniary consideration. At first a number of small baths on the principle of the rain-bath were built, and the results were at once so salutary that later a larger bath was constructed with facilities for about three-hundred and-fifty bathers a day. The rain-bath is to be preferred in this connection to any other form of bath for obvious reasons. No water is actually wasted, and each bather is provided with a fresh supply. The bathing paraphernalia practically cleanses itself, so that the necessity of assistants for this purpose is obviated.

The bath-house of the association consists of thirteen compartments built of corrugated iron below and wire netting above, for ventilation and light. These are covered with white enamel paint, and present an inviting, clean, and fresh appearance. A portion of each compartment is adapted for a dressing-room, and the remainder for the bath-room proper. A period of twenty minutes is allowed each bather, soap and towels being furnished, and the charge for the privilege is five cents. The popularity of the rain-bath is fully attested by the fact that over eighty-thousand persons availed themselves of the privileges of the People's Baths during last year.

The association has also provided Turkish baths, which may likewise be had at moderate cost. A complete apparatus for the therapeutic employment of water has further been constructed, and opportunity is thus afforded physicians of sending suitable cases for treatment.

We cannot speak too highly of this undertaking of the Riverside Association, which deserves the warmest encouragement and support. As the work is, of course, not self-supporting, the association must look to the generosity of philanthropic people for aid in carrying it on and extending its usefulness as the demands upon it increase. The annual fee is $5.00, which may be sent to that indefatigable advocate of water in the prevention and treatment of disease, Dr. Simon Baruch, who is chairman of the Committee on Hygiene.

Venereal Disease in the English Navy.—Judging by the report of the Director-general of the Medical Department of the English Navy for the past year venereal disease is playing sad havoc in the service. There occurred during the year no less than 9321 cases of syphilis and gonorrhea; 3106 of primary syphilis, 1593 of secondary syphilis, and 4622 of gonorrhea and its sequelæ. The number invalided for these diseases was 198, and there were five deaths. 4923 of the cases came under observation at the home station. The ratio of primary syphilitic patients amounted to 51.66 per 1000, as compared with 74.28 in the previous year. The time that the venereal patients were incapacitated from duty amounted in the aggregate to no less than 282,171 working-days. Apart from its moral aspect the subject is one demanding the most profound consideration. With the figures given before us it is difficult to understand why less attention should be directed to the prevention of venereal diseases than is given to that of other transmissible diseases.

The American Academy of Medicine holds its next meeting in Baltimore, May 4th and 6th, and not, as erroneously given in our issue of February 2d, on May 8th. The new line of work undertaken by the Academy has proved of great interest to the members, has excited comment throughout the medical world, and, we doubt not, will prove of great value in the future to the community and to medicine. It is a distinctive and unique function that is now assumed, and one of profound and growing importance. The problems growing out of the dependent classes and of the mutual relations of these classes to the medical profession and to the community give ample scope for lasting labor and best thought on the part of all conscientious physicians. Every eligible physician should join the Academy and contribute his mite to this much needed work. An exceptional program is already promised, and unusual interest is evident in the next meeting.

The Transmission of Typhoid Fever through Vegetables.—The recent agitation upon the subject of the transmission of typhoid fever through oysters has raised the point of the even greater danger of transmitting various infectious diseases through vegetables, such as water-cress, lettuce, and the like. Water-cress more particularly, it has been pointed out, is grown for the most part in beds where it is in contact with the water of rivers and streams that have doubtless often been contaminated with sewage, or it may flourish in a wild state and often in stagnant and unwholesome ponds and ditches. Cases are also on record in which typhoid fever was believed to be transmitted by the use of contaminated vegetables, but the evidence is unsupported by bacteriologic examination.

Gratitude to the publisher of the British Medical Journal is due from his readers for promptly acting upon our suggestion to improve the quality of the paper of the foreign edition. But we are sorry our old friend the *Lancet* persists in its fatal course. We cannot read or quote it so long as printed on such atrocious paper!

SELECTION.

MEDICAL SCIENCE VERSUS HUMANITY.

It is not often that a conflict arises between the humane treatment of a fellow-creature and the desire for knowledge whose ultimate purpose is the relief of suffering humanity. In a certain kind of fiction and in the sensational reports of college experiments and of clinical operations with which the press occasionally seeks to startle and entertain its vulgar patrons, the medical student and his teacher appear in an unfavorable light. Yet the credence placed in such "literature" must be slight, or a genuine hostility against the profession would be engendered. The falsity of such reports is, best of all, shown by the confidence which is reposed in the medical attendant by the very writers of the alleged horrors of the clinic and the amphitheater.

The profession as a whole must plead guilty to the charges of the various societies for the prevention of cruelty to animals, although such charges are usually greatly exaggerated, the intent of the experimenters ignored, and the innocence of the vast majority of the profession entirely overlooked.

But in regard to the treatment of patients, the exhibition of cruelty or negligence is a rare exception. Even those physicians who are generally recognized by their colleagues to be thoroughly selfish and to be restrained neither by fear of God nor love of man, are often the very ones to whom a patient might most safely intrust himself, skill and ambition taking place of benevolence and devotion. We recall a man, despised by his associates who knew him, hated by internes and justly feared by nurses, who nevertheless maintained a large practice and was almost worshipped by many of his patients. Such men, however, are the exception. It seems that the average man upon entering the practice of medicine assumes virtues and a sense of his responsibilities that he would not have attained in any other lifework.

In striking contrast with this estimate of our own medical profession, we note in German literature a tendency to what seems to us a frank and wholly unconscious brutality. For instance, an abdominal section is made to inspect a liver, notwithstanding the almost positive diagnosis of hypertrophic sclerosis. Two pathologists, examining semen-stains in preparing testimony in a case of rape, express their profound gratitude to Professor So-and-so for allowing them to inoculate a culture suspected to contain gonococci into the urethræ of two paralytics in the hospital ward of the latter. Another report describes the antagonistic action of acid solutions on the development of the germs of chancroid, fifteen persons having been inoculated in two places each, one sore being treated as indicated, the other being simply covered with a watch-glass in order to secure a control-experiment.

Such a tendency is to be deprecated, not alone on the ground of sentiment, but because the habit of study purely scientific, as opposed to an endeavor at the same time to relieve suffering, blunts the perception to just those facts that are to be of vital importance to the practical physician. It is the neglect of the humane consideration of his patients that has made the typical German physician a poor therapeutist. The fact that the average medical article in a German magazine contains an elaborate history of cases, an exhaustive discussion of etiology and pathology, an exact though brief synopsis of symptoms and physical signs, a mere allusion to treatment, and, as a matter of course, a minute report of the findings post-mortem, is an index to a trend of medical thought that is opposed to the very existence of a medical profession. It is this trend that has, to some extent, justified the epithet "Hod-carriers of Science," as applied to our German brethren. It has brought about the purely mechanical consideration of the diseased human body. It is logical, if a man is too hot, to plunge him into cold water. The stimulating action of both heat and cold is ingeniously utilized by inducing labor by the alternate administration of a hot and a cold douche. Yet such logic needs the tempering of common sense. Just such therapeutic suggestions as these have led one of the shrewdest of American physicians to say, "I distrust on general principals any therapeutic method originating with the Germans."

We have no sympathy with those who attempt to cover their ignorance of fundamental facts in medicine by denouncing scientific study as impractical. Such men give digitalis in cardiac hypertrophy and aneurysm and try to overcome ether-poisoning with injections of alcohol. Neither do we intend to incriminate the whole German profession, nor to ignore the vast debt of gratitude which we owe them. Nor, again, do we advocate a neglect of scientific study and a return to the benevolent but ill-guided ministrations of a semi-medical priesthood. Let us realize, however, that the ultimate aim of all medical investigators must be practical—in other words, humane. Wherever advantage may be taken of suffering already existing, it is right—indeed, it is a duty to do so. But we cannot condemn too severely the man who inflicts damage to gain information. Occasional infringements on the law of humanity will react on the medical profession to the extent to which they are known by the laity. A general following of such examples will remove our very reason for existence as a profession.—*Editorial in Medical and Surgical Reporter, January 26, 1895.*

Dr. B. W. Palmer, of Detroit, Mich., and for a number of years editor of the *Medical Age*, died on January 4th.

That Day is Lost when St. Louis does not organize a new medical school. The latest is known as the "Practitioners' School of St. Louis."—*Medical Record*,

REVIEWS.

A Monograph on Diseases of the Breast, Their Pathology and Treatment, With Special Reference to Cancer. By W. Roger Williams, F.R.C.S., late Surgeon Western General Dispensary, and Surgical Registrar Middlesex Hospital. With seventy-six figures. 8vo, pp. 572. London: John Bale & Sons, 1894.

The history of opinion and practice in regard to diseases of the breast strikingly illustrates the change that has come over surgery within the past quarter of a century; the transition from vague pathologic theories, uncertain diagnosis, and inefficient treatment, to clearer understanding and more thorough procedure, so that the surgeon of our day can approach his task with a confidence, and his patient may submit with a hope, unknown to those of any former time. But our limited space forbids us to dwell upon this pleasant theme. That the statement made is correct will, we think, appear as we take up some of the chief points presented in the very admirable work now before us.

A very clear and interesting account is given of the anatomy, morphology, and physiology of the breast and nipple, of their anomalies of defect and of excess, and of abnormities of secretion. In the chapter on polymastia, a section is devoted to the neoplasms arising in supernumerary mammary structures.

The histology of the breast in its resting and active stages is described, and the ground is taken that the pathologic neoplastic processes are aberrant repetitions of those of normal development. Such morbid formations are classified according to their derivation, whether from the archiblastic or epithelial, or from the parablastic or connective-tissue elements of the gland. But in reality both tissue-systems are almost invariably represented in every mammary neoplasm.

Carcinomata, properly so called, are of archiblastic origin. They are divided into the acinous, which are by far the more common, and the tubular. They are all more or less malignant; that is, they have an inherent power of continuous undue increase, owing to the indefinitely sustained, excessive proliferative activity of their constituent cells. Their alveoli differ from those of the normal breast-structure, chiefly by reason of the greater number and the disorderly grouping of their component cells. Hence the ancient belief that there was something specific—a "cancer-cell"—was erroneous, and the long search for it was vain; there is departure from the normal type of development, but no foreign structure is produced. According to Mr. Williams, the only real carcinoma and tumor germs are certain cells that abound in all parts growing and capable of growth, and which never become highly developed, but remain in a more or less unspecialized condition.

The chapter on the general pathology of mammary carcinoma is full of interest, especially the section relating to the influence of heredity. Facts are presented showing that this can be traced, either in a direct line or collaterally, in a large proportion of cases; as, for example, in 33 of 136 consecutive instances (24.2 per cent.) of which the author analyzed the records. On the other hand, the causal importance of traumatism is declared to have been greatly overestimated. The author says: "In the vast majority of cases the outbreak of this disease (cancer) appears to be entirely spontaneous; that is to say, it cannot be attributed to the immediate action of any appreciable extrinsic cause whatever."

Another section in this same chapter contains a most remarkable showing, which we quote:

"Prior to 1837, when the Registration Act came into operation, we have no reliable information as to the prevalence of cancer. In 1840 it caused 2786 deaths, the proportion being one in 5646 of the total population, one in 129 of the total mortality, or 177 per million living; in 1890 the deaths due to it numbered 19,433, being one in 1480 of the total population, one in 28 of the total mortality, or 676 per million living. Thus the proportionate mortality from cancer is now about four times greater than it was half a century ago."

It must be remembered that these figures refer to the mortality from carcinoma generally—not from breast-carcinoma alone. The author goes on to say that the number of persons now suffering from carcinoma in England and Wales must be at least 40,000, as against about 5500 in 1840, an increase of something over 600 per cent. Upon what data this estimate is based, other than official records, does not appear.

The curious fact is noted that according to the same records the increase of carcinoma-mortality has affected males much more than females. From 1851 to 1890 it was, as to the former, 167 per cent., but as to the latter it amounted to only 91 per cent.

Another singular statement is that a marked decline in the mortality from pulmonary and other forms of tuberculous disease has coincided with the increase of that from carcinoma. We are not aware whether any other country can furnish statistics for comparison in regard to the results now quoted.

The modern thorough operation for carcinoma of the breast, first suggested by Mr. Charles Moore in 1867, and ably advocated by our brilliant countryman, the younger Gross, is fully described. At present the results obtained by early recognition of the disease, and by the complete removal not only of the gland itself but of all outlying masses and processes, with absolute cleanliness, are far more creditable to the profession, and vastly better for their patients, than those of the best operators of any former period. What changes may yet be devised for its improvement cannot of course be foreseen; but in its present form it imperatively demands universal adoption.

The statistics given by our author as to the relative length of life in cases operated on and in those left to themselves are very strongly in favor of interference as the rule.

We would gladly discuss other portions of this work, which is full of evidence of the intelligent research and painstaking labor devoted to its preparation. The various forms of non-malignant breast-tumors, the axillary neoplasms, and the inflammatory disorders as observed in both sexes, are described at length and with many illustrative case-histories. But we have reached the limit of space allowed us, and can only hope that this brief notice will serve to induce a general study of one of the most important of recent contributions to surgical knowledge.

It is to be desired that in any future edition the proof-reading will be more carefully done. Many typographic errors offend the eye; in one instance the omission of the word "no" inverts the significance of a case quoted from Bryant.

RELATIONS OF DISEASES OF THE EYE TO GENERAL DISEASE. By MAX KNIES, Professor Extraordinary at the University of Freiburg. Forming a supplementary Volume to every Manual and Text-Book of Practical Medicine and Ophthalmology. Edited by HENRY D. NOYES, A.M., M.D., Professor of Ophthalmology and Otology in Bellevue Hospital Medical College, etc. Octavo, pp. 470; illustrated. New York: William Wood & Co., 1895.

THERE are two or three titles to this book, with decided differences of meaning. "The Eye in General Disease," has to our mind a very different meaning from "The Relations of Diseases of the Eye to General Diseases." The editor says of the book that "the alliances between the eye and the rest of the body are so admirably traced, etc.," and in the author's preface the function of the book is repeatedly emphasized as the setting forth of the relationship between diseases of the eye and diseases of the rest of the body. Despite all this, we are astonished to find that the second sentence of the book reads as follows: "It is rare to find eye-diseases[1] the starting-point for diseases of the nervous system." Observing that this rule consciously or unconsciously is the governing idea of the whole volume, we conclude that the titles, one and all, are utterly misleading. There is no attempt whatever to treat of ocular abnormalities as the cause of extra-ocular disease; on the contrary, there is a disbelief in the fact. The book treats solely of extra-ocular disease as productive of ocular abnormality, and is a valuable gathering of facts pertaining to this restricted field of study. But it must not be forgotten that the title of the book is inverted and wholly misleading. The author knows nothing, at least not a word in the volume would betray the knowledge, of ametropia and abnormalities of ocular balance, either as ocular diseases *per se*, or as capable of setting up disease elsewhere. Now, it is precisely these ocular diseases and their extra-ocular reflexes that occupy nine-tenths of the time and the attention of many American ophthalmologists. One finds no hint in the index or in the text even of headache as caused by eye-strain. It is the same with all reflex neuroses starting in the eye. The exhibition of this astounding oversight in a book written with evident conscientiousness and scientific purpose shows how far apart are to-day the two great schools of ophthalmology. Thousands of articles and facts are utterly ignored by such writers as the author in order to preserve the apparent consistency of a prejudice. The writer who in 1894 pretends to set forth the relations of ocular and general disease without even mentioning the fact of headache, and of functional, gastric, assimilative, and nervous abnormalisms of a hundred kinds due to the eye, should spend an hour in a good refractionist's office, and then go home and keep silent for the rest of his mortal or immortal life.

We would also protest against the non-honoring of the translator. Scholarship should have its reward, not only of pay in money, and the reader should also have the guarantee of a name, that the translation is well done.

TEXT-BOOK OF ANATOMY AND PHYSIOLOGY FOR NURSES. Compiled by DIANA CLIFFORD KIMBER, Graduate of Bellevue Training School; Assistant Superintendent New York City Training School, Blackwell's Island, N. Y.; formerly Assistant Superintendent Illinois Training School, Chicago, Ill. New York and London: Macmillan & Co., 1894.

THE appearance of a text-book on anatomy and physiology, prepared especially for the use of nurses, in which can be found a clear and systematic arrangement of both subjects, will be heartily welcomed by both teachers and pupils of training schools. For, while by its aid the teacher will be saved an infinite amount of trouble and time spent in rearranging notes, in looking up references, and in making long explanations, which she can occupy much better in perfecting her lectures, the pupil will be enabled to follow the oral teaching with much greater ease and intelligence.

Looked at from another standpoint, such a book as that of Miss Kimber's may be regarded as one of the favorable signs of the times, in that the very necessity for its publication would go to show the high standard of education which is now expected of a nurse trained on broad scientific principles. Even the doctors have now ceased to declare that a knowledge of the anatomy and functions of the human body is not essential to the highest type of nurse, since they have found that the more intelligent the nurse, the more valuable her assistance and the more reliable her work, especially in the face of an emergency. Certainly in the past more than one life might have been saved when the nurse was left alone to deal with cases of severe hemorrhage had she known the location of the bleeding vessel and when compression should be made in such cases, and this is only one of many instances that might be cited.

Of late years physicians have very properly laid much more stress on the quality and proper preparation of the food to be given their patients. For carrying on this part of the treatment the nurse must be mainly depended upon, and she cannot do this intelligently unless she is conversant with the subject of alimentation. In her chapters on this subject, Miss Kimber deals minutely with the various changes that go on in the digestive tract, and puts before the student the result of recent researches in a very readable form.

The division of the book into lessons as well as into chapters is most helpful. The illustrations are clear and very well selected with a view to object-teaching in connection with the lectures. We congratulate the pupil-nurses of the present day upon having such a valuable help in their course of instruction.

THE THEORY AND PRACTICE OF MEDICINE. By FREDERICK T. ROBERTS, M.D., B.SC., F.R.C.P. Ninth edition, 8vo., pp. 1168. Philadelphia: P. Blakiston, Son & Co., 1894.

THIS edition of *Roberts' Practice* requires no elaborate commentary. The mere fact that the work has reached its ninth edition is sufficient evidence of its merits and the favorable reception that has been accorded it. The work has been carefully revised throughout; in parts rewritten; and a number of new subjects have been introduced. Sections dealing with the general therapeutics of the principal systems and organs of the body have also been added. There are, however, a few criticisms that seem justifiable. It appears to us that scarcely sufficient importance is attached to the utility of the Brand method of treating typhoid fever. As a matter of fact, the exact mode of procedure is not given in detail. Those who use this method most contend, with justice, that the results obtained with modifications of the original are not at all comparable with those obtained by the method itself. Although the edition bears the date of October, 1894, no reference is made to the treatment of diphtheria by the use of the antitoxin. The section upon influenza lacks the detail in description that the importance of the subject would seem to entitle it to. It appears, too, a little arbitrary to separate the general consideration of the subject of tuberculosis from that of the pulmonary variety. Notwithstanding the criticisms that have been offered, the book easily maintains the prominent position that it has attained as a text-book for both medical student and practitioner.

[1] The hyphen is omitted in the original, as almost everywhere else that a compound term is used.

CORRESPONDENCE.

ERYTHEMA NODOSUM.

To the Editor of The Medical News,

Sir: Marked cases of erythema nodosum being rather rare, the report of the following case may be of interest:

Mrs. H., fifty-seven years of age, for several years a subject of chronic nephritis and of frequent digestive disturbances, was reported as having an attack of hives. I prescribed, and was called next day, as she was worse. I found half a dozen red lumps, not unlike hives in appearance, on the right wrist, while the wrist, hand, and fingers were considerably swollen, painful, and throbbing, the pain extending up the arm to the axilla. The temperature was 100°, the pulse small and rapid. There was a history of a fishbone stab in the same hand, and the patient complained of slight chilliness at times and of profuse sweats. The possibility of septic infection was seriously considered. Upon the next day, the third day of the attack, the eruption extended further and appeared on the left wrist; the edema was greatly increased, and the temperature had risen half a degree. On the fourth day both arms were involved to above the elbows; there was great discomfort; and the temperature was 102°. On the fifth day the eruption appeared profusely and suddenly on both legs, and the temperature was 104°. There was profound prostration, great swelling of the affected parts, with lumps varying in size from a split pea to a hen's egg and larger, and pain of a deep throbbing and aching character and quite severe. There were nearly one-hundred distinctly separate nodes, besides a number that were confluent and counted as one.

The treatment was purely symptomatic and, except for the lead-and-opium lution, which was grateful locally, seemed to have absolutely no effect.

After the fifth day the temperature fell rapidly to below 100°, where it remained, as the local symptoms abated, only to rise slightly and fall again with each of the three successive crops of the eruption, occurring at intervals of from three to seven days.

The whole duration of the attack was four weeks. It was followed by deep and abundant desquamation and gradual restoration to the normal of the affected parts.

The points of interest in the case were:

1. The degree of fever and marked general depression.
2. The profusion of the eruption.
3. Its location primarily and chiefly on the arms.
4. The advanced age of the patient.
5. The unusual character of the pain.

Respectfully yours,

W. W. Anderson.

Newport, Ky.

FOOT-BALL CASUALTIES AT LOUISVILLE.

To the Editor of The Medical News,

Sir: During the past season Louisville had several foot-ball teams that demanded attention—two High School teams, between whom the rivalry is great, and the team of the Louisville Athletic Club, with which I was associated as surgeon. The latter team played games on their own grounds with eight visiting college teams, and in all but one game were the services of a surgeon demanded.

The following is a list of the casualties: Cut over eye, 6; scalp-wound, 1; fracture of second phalanx of little finger, 1; sprain of knee, 3; sprain of ankle, 1; re-sprain of ankle, 1; bruised shoulder, 1; dislocation of acromion end of clavicle, 1; bruised sciatic, 1; synovitis of toe, 1; broken rib, 2 (different men); venous aneurysm of arm, 1; fracture of leg, 1; total number of accidents, 21. Two of the sprained knees were of visiting players. The cuts over the eye, with one exception, needed one or two stitches to effect approximation, and were all caused by the player being hit with another's head.

These figures show conclusively that some radical change of the existing rules must be made. The larger percentage of accidents among the home teams can be explained in part, at least, by the fact that but two or three of the players were "in training"—they were in no condition to undergo any violent exercise.

All of the trained players, the members who had played on college teams before joining the club team, almost without exception came out of every game uninjured. The majority were smokers—some to excess—some were drinkers, and oftentimes the game would be played directly after eating a hearty meal; while exactly the opposite condition of things prevailed among the college teams.

A broken leg of one of the High School teams shows the severity of the injuries that can happen to inexperienced and untrained players.

I am a great admirer of the game from purely an athletic standpoint, and believe that a few judicious changes in the rules will make foot-ball a clean, invigorating game; as it is now, there are many more chances for injuries to be received than from other athletic sports.

Very truly,

Henry E. Tuley.

111 W. Kentucky St., Louisville, Ky.

A SIMPLE AND INEXPENSIVE FACE-PROTECTOR FOR THROAT-EXAMINATIONS.

To the Editor of THE MEDICAL NEWS,

SIR: The following describes the method of making a face-protector for examining the throat, and costing only about four cents:

Take a pasteboard shoe-box, and through the bottom cut two eye-holes, each one inch square and about midway between the two ends of the box. The lid is not used. Through one side of the box, close to the bottom, cut a narrow slot opposite to the eye-holes, two inches long, and through this slot pass a strip of window-glass, two inches wide and a little longer than the width of the box, measured externally. This glass will thus pass behind and cover the eye-holes. One end of the glass is notched to fit into a smaller slot in the other side of the box and a strip of adhesive plaster closes the long slot and holds the glass in place. The box fits over the face and is held in place by a cord or gum-elastic. It protects the face in front and at both sides, and fits under the chin and over the top of the head. After each examination burn the box and fit the glass, after disinfection, to a new box. The glass costs practically nothing, and lasts indefinitely.

A new box may be fitted up in a few minutes. The glass may be carried in the pocket and attached to a box at the patient's house. Having been called hurriedly to a case of diphtheria, and having nothing of the kind then at hand, I hastily improvised this primitive and rude device. As it has proved to be entirely satisfactory I shall continue to use it.

Respectfully, B. F. R. CLARK.

4037 LOCUST ST., PHILADELPHIA.

NEWS ITEMS.

The American Academy of Medicine will hold its twentieth annual meeting in one of the buildings of the Johns Hopkins University, Baltimore, on Saturday, May 4, and on Monday, May 6, 1895.

The following are the titles of the papers that have been promised: "The Address of the Retiring President, J. McFadden Gaston, Atlanta, Ga.; "Expert Testimony," Henry Leffmann, Philadelphia; "Hospital Management," W. L. Estes, South Bethlehem, Pa.; "The Proper Teaching of Physiology in the Public Schools as a Means of Preventing Intemperance and Venereal Disease," De Lancey Rochester, Buffalo, N. Y.; "The Problem of Dependency as Influenced by the Chinese in America," W. F. Southard, San Francisco; "What Agencies Conspire to Check Development in the Minds of Children," J. Madison Taylor, Philadelphia; "How to Avoid the Dispensary Abuse?" Emma B. Culbertson, Boston; "Contract Medical Work and Fees," Charles P. Knapp, Wyoming, Pa.; "What Shall We Do With Our Alcoholic Inebriate?" J. W. Grosvenor, Buffalo, N. Y.; "Life Insurance in its Relation to one of the Dependent Classes," E. O. Bardwell, Emporium, Pa.; "Some Results of Competitive Medical Charity," George M. Gould, Philadelphia; "Criminal Anthropology," E. V. Stoddard, Rochester, N. Y.; title to be announced, Leartus Connor, Detroit, Mich.; "The Increase of Insanity," Gershom H. Hill, Independence, Ia.; "A Perfect Consultation," L. Duncan Bulkley, New York; "An Analysis of the Reports of the Examinations by the State Boards of Medical Examiners," Perry H. Millard, St. Paul, Minn.; "The Limits of a Physician's Duty to the Dependent Classes," James W. Walk, Philadelphia; "The Economic Aspect of American Charities," Bayard Holmes, Chicago; "Is Our Financial Relation to Our Patients and Community the Best Possible?" Woods Hutchinson, Des Moines, Iowa.

Dr. Erasmus Darwin Safford died January 6, 1895, at Parkersburg, W. Va. He was born at Point Pleasant, Mason County, W. Va., July 1, 1819. His father, grandfather, and great-grandfather had been successful physicians, so that early in life he naturally turned to the study of medicine. After assiduous reading with his father he soon was enabled to take a course of lectures in the old Pennsylvania University at Philadelphia, where twenty years before his father had attended.

In the spring of 1841 he assumed the practice of his deceased father in Parkersburg, and at once became successful. In August, 1862, he was appointed Surgeon-major of the Sixth Virginia Volunteer Infantry, serving with skill and honor until the close of the war. Because of injuries to his health incurred during the exposures on the field during this period, he had since the war gradually relinquished active practice.

Dr. Safford was particularly skilful in diagnosis, and remarkably successful in the treatment of the diseases of women and children. In an extensive practice, covering a period of forty-eight years, only one case of obstetrics resulted fatally, and in this instance delivery was preceded by a heavy fall, causing internal hemorrhage. His treatment of typhoid fever was equally successful. He was a great student, and kept informed through the latest publications. A man of brilliant mind, with the enthusiasm of the student, loyally devoted to the highest medical ethics, with unusual professional skill united to a womanly tenderness, Dr. Safford possessed a rare nature which, under favorable environment, would have made his fame more than local.

Dr. Samuel K. Ashton, a well-known physician of Philadelphia, died February 11th, at the age of seventy-three years.

THE TREATMENT OF SYPHILIS WITH INTRAVENOUS INJECTION OF MERCURIC CHLORID.

BY WALTER LYTLE PYLE, A.M., M.D.,
OF WASHINGTON, D. C.

THE object of this paper is to present a new treatment of syphilis, which has been particularly successful in the hands of Italian physicians for the past two years. Recent reports of syphilographers indicate a tendency to supersede the older methods of treating syphilis, such as by oral medication, baths, vapors, inunctions, etc., by some speedier and more certain method. Dr. L. Wolff, of Philadelphia,[1] in a very admirable paper, in which he has embodied reports from many Continental observers, proves conclusively that the hypodermic administration of the salts of mercury is not only a warrantable, but an advisable procedure, possessing decided advantages. It is naturally open to many objections, and has been fully discussed by competent critics. It is not in the province of this paper to reopen this discussion, but to describe a new method, which obviates many of the objections to the hypodermic injections; to give a dispassionate review of it, and to excerpt from reports of cases from the Italian in which a thorough trial of the treatment has been made.

At the present time it is impossible to report any cases under personal observation, as a satisfactory or trustworthy report cannot be made until the treatment has been given at least several months' trial.

The intravenous injection of mercuric chlorid in the treatment of syphilis was originally suggested by Prof. Guido Baccelli,[2] of Rome, who had previously been quite successful in the treatment of the pernicious as well as the other forms of malarial fever by the intravenous injection of the salts of quinin. The good results obtained in this manner impressed Baccelli with the advantage of direct medication to the corpuscular elements of the blood in certain phases and types of disease. At first it was thought that the drug would cause coagulation of the blood, but experiments on the lower animals proved the contrary. Baccelli injected a dog intravenously, with a solution of mercuric chlorid, 1 : 1000, until five centigrams of the salt were injected in a single dose without subsequent toxic symptoms and only slight salivation. He then directed his experiments to the treatment of some obstinate cases of organic syphilis, which had resisted all other treatment, by the intravenous injection of mercuric chlorid 1 : 1000, commencing with doses of 0.001 gram. (equivalent to 1 gram of the solution) and progressively increasing the dose to .005 gram. His investigations met with the most brilliant results, and since then thorough investigation into the merits and value of the method has been made by Baccelli, Jemma, Colombini, Nieddu, Campana, and many others throughout Italy.

In the preparation of the fluid for injection the following formula is used:

Mercuric chlorid	1 grm.
Sodium chlorid	3 grms.
Water	1000 grms.

A small quantity of alcohol may be added to facilitate solution. The mixture should be well stirred, and filtered until perfectly clear. It is advisable, but not necessary, to sterilize it, both to be perfectly aseptic and to facilitate solution.

A ligature is applied above the elbow, and any one of the superficial veins in the neighborhood, which soon become prominent, may be selected as the point for injection. The point selected and the surrounding area are then thoroughly scrubbed and disinfected with a 1 : 1000 solution of mercuric chlorid or a 5 per cent. solution of carbolic acid. The needle, previously sterilized, is plunged directly toward the center, at the point selected, and a few drops of blood allowed to ooze out, assuring entrance into the vein; the barrel is carefully applied, avoiding any entrance of air.[1]

Loosen the ligature and make the injection, at first using only one gram of the solution, and progressively increasing to four grams at a dose. Occasionally on the withdrawal of the needle there is some extravasation of blood into the neighboring subcutaneous tissue; but this is absorbed very quickly, and is only of occasional occurrence. Repeated injections can be made in the same vein. In a case reported by Jemma seventy-five injections were made in the median cephalic vein. This vein and the median basilic are the best to use.

[2] Gaz. med. di Roma, 1893, xix, 241–245.

[1] Recent experiment has shown that a small quantity of air can be injected intravenously into a rabbit without any harmful effect.

There are two precautions that should be remembered: First, always use a fresh solution, which the physician should prepare himself, to be assured that the salt has not decomposed, which is often the case after the solution has been standing some time. No after-dressing is needed, and it is not necessary to cover the wound of puncture with collodion. Second, do not use a concentrated solution. That of 1 : 1000 is to be preferred, but in late injections a 1 : 500 solution may be used.

The following extracts of cases reported by Baccelli will convey the degree of usefulness of this treatment:

CASE I.—A man, twenty-eight years of age, contracted syphilis in February, 1890. He was first seen in February, 1892, two years after the appearance of the initial sign, with distressing symptoms of cerebral syphilis, and he was completely blind. From May until December, 1892, energetic treatment with van Swieten's solution, mercurial inunctions, potassium iodid, and hypodermic injections of calomel proved of no avail, and the symptoms remained the same, with only a slight alleviation of the persistent headache. In spite of this, the original diagnosis of a syphilitic tumor at the base of the brain was adhered to, and on January 3, 1893, the intravenous injections were begun. The initial dose was one gram of the standard solution, which was gradually increased to five grams. On February 19th, after twenty-eight injections, all the other symptoms had disappeared, and the blindness, which was before complete, began progressively to improve.

CASE II.—A man, fifty-five years of age, suffered from a syphiloma of the tongue. Local treatment with the ferric chlorid, silver nitrate, the actual cautery and ordinary syphilitic treatment gave negative results, and injections were commenced. After twenty-four the improvement was so marked that a permanent cure seemed certain.

CASE III.—The patient had stenosis of the bronchi, due to syphilis, and there were severe attacks of suffocation, resembling asthma. The attacks have since disappeared after a short course of injections.

Baccelli tried intravenous injections in several cases of erysipelas with success, as follows:

CASE IV.—The patient had erysipelas of the gluteal region, and was subjected to intravenous injections of the standard solution in the ordinary manner, with a resultant cure in four days.

CASE V.—In a case of erysipelas of the face a cure was effected in three days by intravenous injections.

R. Jemma, of Genova, reports the following cases:[1]

CASE VI.—A man, thirty-eight years old, suffered from cerebral symptoms of one year's duration, the most prominent of which were a general pseudo-paralysis, Romberg's symptom, and diminution of sight and hearing on both sides. Seventy-five injections were given. His general state was markedly improved. The former weakness and pain disappeared. The patient walked without the aid of a stick. The sight and hearing steadily improved and were progressing toward recovery. He was yet under treatment.

CASE VII.—The patient was a man, thirty-one years of age, who contracted syphilis three years previously to applying for treatment. On application he showed symptoms of cerebral syphilis, the most prominent being daily epileptiform convulsions. Beginning with 0.001 g. of the salt and increasing to 0.003 g., twenty injections were made. After the first injection the improvement was marked. The convulsions decreased, and at the time he left the clinic the man had not had a convulsion for eight days. His power of speech improved daily, and a cure was expected. Previously to the injections inunctions of mercury and large doses of potassium iodid had proved of no avail.

CASE VIII.—A woman, twenty-five years of age, had contracted syphilis four years previously, and on presentation at the clinic was suffering with constitutional symptoms Among these were oligemia and multiple neuritis. She had been confined to bed for some time, and had resisted all treatment. Mercurial inunctions and large doses of potassium iodid resulted negatively. Intravenous injections of mercuric chlorid were administered, and improvement was almost immediate. She left the clinic greatly improved.

CASE IX.—A man, twenty-seven years of age, contracted syphilis one year previously, and was suffering from constitutional symptoms and syphilitic adenopathy, together with the pains of neuritis. Sixty injections were given and were followed by steady improvement. The pains disappeared, and the ganglionic tumefaction diminished. The patient was still under treatment.

Dr. Jemma also employed intravenous injections of mercuric chlorid in six cases of typhoid fever, one of rheumatism, one of erysipelas and one of tuberculosis, but had purely negative results. One of the typhoid cases improved after the injection, but there was no influence on the temperature.

M. A. Dagnino,[1] in the clinic of Secondi, of Milan, reports the case of a man, twenty-three years of age, suffering from syphilitic iritis, showing pinkish-yellow nodules on the iris, who was cured in thirteen days, using in all 0.032 g. of mercuric chlorid. P. Colombini[2] has treated eighteen cases with varying degrees of improvement. In some cases, however, the treatment was suspended on account of salivation or diarrhea. Dr. Antonio Nieddu[3] has reported seven cases, all of which have shown great improvement. In fact he says that after four or five injections improvement was marked, and ultimate good results were invariably obtained.

The disadvantages of the older methods of medication in syphilis are well known to every one. Thorough exposition of the hypodermic injections has been made by the papers of Dr. Wolff, Dr. J. William White, and others, and it may be advisable to present the merits of the injections proposed in the treatment of syphilis and to give the reasons that I consider valid for and against their use:

1. There is absolute certainty of absorption, which cannot be obtained by hypodermic or other methods.

2. There is no pain to speak of. Intra-muscular and hypodermic injections are very painful. The subconjunctival injections in the treatment of syphilitic iritis are impracticable on account of the pain. This method is as successful with no pain. Not a single patient of all those reported has objected to the treatment. In using the hypodermic treatment it is not possible to use any local anesthetic successfully.

3. There is no disturbance of the digestive tract during treatment. In fact, a slight salivation and diarrhea, temporary only, are the only local disturbances reported.

4. There is more rapid absorption and therapeutic effect than by any other method.

5. Less of the mercurial salt is required.

6. Absolute exactitude of dosage can be obtained, which is a rational necessity. Owing to variations in absorption, this is the only method that offers this advantage.

7. It seems to be completely safe; not one accident has been recorded.

8. It is perfectly reliable. All cases reported have shown some improvement, and never any retrogression.

9. Abscesses are absent. These cannot always be avoided in the hypodermic method.

10. There are no dermal irritations or eruptions, such as follow friction or inunctions.

11. The hysteric or nervous symptoms sometimes associated with the hypodermic method are never observed with the intravenous injections.

12. It is successful often when all other methods fail.

13. There is no history of recurrence after a cure.

14. Mercuric chlorid has a preservative action on the red blood-corpuscles, and hence must be valuable intravenously in such a disease as syphilis, in which there is a strong tendency toward destruction of the red blood-corpuscles and subsequent anemia.

The objections offered to the intravenous method may be summarized as follows:

1. In the early stages of syphilis the lesions are in the skin and connective tissue, and, therefore, intravenous injections do not offer the most immediate and satisfactory method of medication.

2. Syphilitic gummata have no vascular supply, and the intravenous injections do not directly reach them. Despite this fact, it is more than probable that the gummata are influenced by mercurial medication as rapidly by the intravenous injections as by any other method.

3. There is a belief that mercuric chlorid, intravenously, has only a temporary action, being quickly eliminated, necessarily making the treatment longer in such a case than with hypodermic injections of solutions of insoluble salts (Columbini).

While it is true that insoluble salts are eliminated more slowly than the soluble, and hence have a more permanent effect, yet observation of the relative merits of soluble and insoluble mercuric salts has shown that mercuric chlorid has a decided preference and gives the most satifactory results generally. Dr. Wolff's communications verify the foregoing statement. This is most likely due to the rapid absorption and action of the drug in contradistinction to the slow and uncertain absorption of the insoluble salts. Uncertain elimination and absorption are always unsatisfactory factors to deal with in therapeutics, and complicate any attempt at definite and scientific treatment.

The disadvantages of the intravenous injections are as follows:

1. The needle may not reach the vein; but this can be remedied by applying the needle first and awaiting the appearance of a few drops of blood.

2. Some of the blood may extravasate into the subcutaneous tissue, adjacent to the point of injection; but this has been of very rare occurrence, and the blood is soon absorbed.

3. There is likely to be a slight stomatitis at first.

4. There is the appearance of albumin in the urine after the injections, which, however, is also often resultant on the hypodermic administration.

5. There is, as in all intravenous injections, a subsequent polyuria and increase of urea, but neither has any special disadvantage.

6. During the injection, through a reflex action on the circulatory center, fainting may supervene, but is of no vital import.

7. Jemma has seen slight salivation immediately after the injection of small doses. This is liable to happen in any administration of mercury.

Conclusion. The advantages shown so far overbalance the objections that, viewing the present status of treatment, we can but accept this as the most successful at our hands. However, I would not advocate it in cases easily amenable to ordinary treatment or in the early stages of syphilis, but consider it of especial value in the obstinate cases, resisting other treatment, or in advanced cases of organic syphilis, or when immediate relief is peremptory by reason of pain, encroachment on a vital part, or rapid destruction of tissue. Investigation may prove it to be most valuable immediately after the diagnosis is made, eliminating or destroying the syphilitic virus before it has produced any decided effect on the general system. At present there is no evidence to warrant this statement; but, as the method is virtually devoid of dangerous or untoward results, it should be given some trial in the beginning of the disease. When the disease is modified by the intravenous injections, it is very probable that the treatment may be continued successfully by the common methods.

Viewing the brilliant results in the cases reported, it would seem that this method is a most valuable one, and one which, in the hands of careful practitioners, will render all forms of this dreadful and everlasting scourge readily curable. It certainly deserves careful study and thorough trial in the hands of American physicians. I should be glad to receive any communications relative to this subject, and trust the method will be given thorough test and discussion.

1701 H STREET, N. W.

OPHTHALMIA NEONATORUM.[1]

BY C. A. VEASEY, M.D.,
CHIEF CLINICAL ASSISTANT TO THE OPHTHALMOLOGICAL DEPARTMENT OF THE JEFFERSON MEDICAL COLLEGE HOSPITAL; INSTRUCTOR IN DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC; CONSULTING OPHTHALMIC SURGEON TO THE PHILADELPHIA LYING-IN CHARITY AND NURSE-TRAINING SCHOOL.

I SHALL not now attempt to give any elaborate description of this disease, nor shall I review very many of the methods of treatment as practised by different ophthalmologists, but shall confine myself to the characteristics as they appear in typical cases and to those methods of treatment that have in my own hands given the most satisfactory results.

The clinical history of the disease is usually divided into four stages; but as it passes from one into another so imperceptibly it is often difficult, if not impossible, to make any distinction between them. The first, or incubative period, is of short duration, lasting a few hours only, and gradually merges into the second, or lymph-forming stage. This, in a few hours more, is followed by the period of pus-formation, lasting, according to the severity of the attack, from one to several weeks, and if everything goes well is replaced by the last stage, that of recession, which is marked by the gradual disappearance of the discharge and the return of the conjunctiva to a healthy and normal condition.

The appearance of a patient suffering with this affection is so characteristic that it is rare for any mistake to be made in the diagnosis. Appearing, as it usually does, on the third day after birth, though it may appear somewhat earlier or later, with a slight redness of the conjunctiva, the lids are soon swollen and tense, the conjunctiva itself velvety and smooth, and upon the surface of which can be detected minute flakes of lymph. In an exceedingly short time, however, the formation of lymph changes to the profuse secretion of pus, the conjunctiva frequently displaying huge cracks in its surface and occasionally being so tender that there is an admixture of blood with the purulent discharge. In mild cases the ocular conjunctiva is scarcely more than hyperemic, but in many it becomes hard and tense, forming an elevated ring around the cornea. Occasionally the upper lid is so heavy from the swelling that it becomes pendulous and hangs down over the margin of the under lid. The disease, which ordinarily has begun in one eye, usually affects the other also, though, as a rule, not in such a severe degree. There is present, of course, severe pain, and the infant's physical condition is much reduced, as would be the case no matter in what part of the body so much pus was being formed.

In most cases in from three to six weeks, if seen early and proper treatment instituted, the discharge gradually disappears, leaving the conjunctiva in a healthy condition and the visual acuity unimpaired, though in a few there remains a chronic conjunctival inflammation.

In all cases the greatest danger is from some corneal complication. It may begin as a mere abrasion of the cornea from rough handling, which if it occur during the pus-forming stage may result in a large perforating ulcer. Again, the whole cornea may become infiltrated and opaque, small abscesses forming, which may open externally, or into the anterior chamber; or the ulceration may begin at the margin and extend in a ring-like manner around the cornea, there being but little infiltration of the corneal substance, and, as Swanzy[1] has pointed out, these are likely to occur in those cases in which the swollen bulbar conjunctiva forms a hard ring around the cornea, causing considerable pressure, occasionally even covering the ulcer, and are likely to perforate. The greater the involvement of the ocular conjunctiva and the earlier the corneal complication manifests itself, the more serious does the disease become and the more likely is it to result in some impairment of vision, if not absolute blindness; for if the ulcer should perforate, the anterior chamber empties itself, the iris usually becomes incarcerated, and the thinned cornea, unable to resist the pressure, bulges forward more and more until a large anterior staphyloma results; or, on the contrary, after perforation takes place, the eyeball may shrink in size until that condition of affairs known as "phthisis bulbi" is reached.

---

[1] Read before the J. M. Da Costa Medical Society, December 7, 1894.

[1] Swanzy: Text-book, "Diseases of the Eye," p. 101.

The etiology of the affection is the introduction into the conjunctival cul-de-sac of the discharge from some portion of the genital tract, and the inoculation may take place during the birth of the child, when it is said to be primary, or the infecting material may be placed *in situ* after birth through the carelessness of the attendant, the inoculation in this case being secondary, and the disease manifesting itself later than the third day.

During the descent of the infant through the birth-canal the inoculation may occur in one of several ways. The lids may be opened in making manual examinations in face-presentations, or in the use of instruments, or in the passing of the face over the tense perineum; and the eyes not being quickly and thoroughly cleansed after birth, the infectious material obtains a footing and the disease becomes rapidly established. Those cases in which the inoculation is secondary are caused by the direct introduction of the infectious material by the use of unclean water, sponges, towels, etc., or, perhaps, through the failure on the part of the attendant to have everything coming in contact with the infant thoroughly cleansed.

The underlying cause in most cases is a peculiar micro-organism known as the gonococcus of Neisser, which the discoverer after whom it is named found in all gonorrheal discharges and also in the discharges of all severe cases of ophthalmia neonatorum, though we occasionally see slight cases set up by a vaginal discharge of a non-specific type, and in these the gonococcus is, of course, absent. The more numerous the gonococci, the more severe and dangerous is the disease; and, on the contrary, when the number of these micro-organisms begins to decrease, as shown by microscopic examinations of the discharge, the disease is becoming more controllable and less dangerous.

In discussing the treatment it is customary to do so under two heads—prophylactic and curative. Among the means at our disposal which come under the former heading none is more widely known, or gives better results if used, than that which was introduced by Professor Crédé, of Leipsic. As soon as the child is born, and before the cord is cut, if there is time, two drops of a 2 per cent. solution of silver nitrate are dropped into each eye of the infant, the lids and surrounding parts having first been cleansed with a pledget of absorbent cotton. If there is much reaction, compresses are wrung out in a cold solution of boric or salicylic acid, and placed on the closed lids. Sometimes there is considerable hyperemia from the use of the silver-solution, but it almost always disappears in a few days; and, when we consider the great gain by the use of this preventive method, the slight inflammation is not any drawback. Prior to the use of the method Crédé's statistics showed that 10 per cent. of all newly born children had this disease, while after its use the proportion was reduced to less than one-half of 1 per cent.

Another method of prophylaxis is that known as the Hegar-Korhr, which consisted in washing the face and eyes of the newly born babe with a solution of mercuric chlorid (1 : 1000), and this also gives a large reduction in the proportion of cases of the disease. Others advocate the use of aqua chlori, claiming that it is fully as effective and less irritating than the solution of silver. Perhaps, after all, it is not so much what method of prophylaxis we use as the fact that we do use some method, and use it thoroughly. It is to be understood that no matter what method is adopted after the birth of the child, during the descent through the birth-canal all precautions against infection, such as antiseptic vaginal douches, thorough cleansing of the hands and all instruments, etc., coming in contact with the parts, are to be most scrupulously effected.

Since the time of the introduction of antiseptic midwifery and the decrease in the percentage of those diseases caused by the absorption of germs from the genital tract, it is perhaps unnecessary to use silver nitrate in each and every case, provided the most scrupulous care be exercised to keep the birth-canal aseptic during labor; but in each case in which there is the least suspicion of specific disease, or even a moderately bad leukorrhea, in addition to the strictest antiseptic precautions during the birth of the child, I would insist upon the use of the Crédé method, or one of its recognized substitutes, immediately afterward.

If the disease has become established, our efforts must then be directed, first, to the reduction of the inflammatory condition of the lids and conjunctiva; second, to the prevention of any corneal complication, or the treatment of any already existing. If there is much swelling, and there be no involvement of the cornea, I prefer to employ cold compresses at frequent intervals. These are applied by having a number of small pieces of flannel or lint laid upon a block of ice, and placing them, two or three in thickness, over the inflamed and swollen lids, changing them at intervals of one minute. These are to be used from fifteen to thirty minutes, every hour or two, or less frequently, according to the severity of the disease. Should there be any corneal involvement, however, hot compresses should be employed instead, in the same manner and at the same intervals as the cold, water at the temperature of 120° F., or about as hot as the hand can bear for an instant, being used instead of the block of ice. As the water grows cooler more hot water should be added to keep up the temperature.

Great care must be exercised to keep the conjunctival cul-de-sac cleansed of the purulent discharge. This can be accomplished by frequent washings with a saturated solution of boric acid or a weak solution of mercuric chlorid (1 : 6000), cleansing the eyes at intervals of fifteen minutes, or less frequently, according to the amount of the discharge, to be continued during the night as well as during the day. Frequent cleansing of all the discharge from the lids is of the utmost importance. Other solutions have been used for the purpose, such as mercury cyanuret, potassium permanganate, hydrogen dioxid, creolin, chlorin-water, trikresol, pyoktanin, and many of the astringents; but the two mentioned first, boric acid in a saturated solution and mercuric chlorid in the strength of 1 : 6000, are probably as efficient as any, acting, as they do, only feebly as antiseptics (it being detrimental to the cornea to use strong solutions of the mercurial), but also as astringents.

Once a day, when the conjunctiva is in the proper condition, the lids being everted, an application to them of a solution of silver nitrate should be made with a camel's-hair brush or a bit of cotton rolled on the end of a smooth stick (both to be burned immediately afterward) and the excess washed off with a solution of sodium chlorid. It is preferable to begin with a moderately weak solution, say 1 per cent., and increase the strength if necessary. Occasionally it is necessary to use the mitigated stick, and, if this is done, great care must be exercised to wash off the excess, otherwise damage may be done to the cornea.

I wish to enter my protest against the method practised by some physicians of dropping the solutions of silver nitrate into the conjunctival cul-de-sac, so that they come in contact with the cornea, as a remedy to be continued. They will do no harm when dropped in immediately after the birth of the child, and again in a day or two if required; but the continuous use of the drug, day after day, in this manner, will in itself cause an opacity of the cornea by its caustic action—a thing to be studiously avoided and a complication which is inexcusable. I have under my care at the present time an infant on whose eyes this method of using the silver-salt was employed, and it has a milky haziness in each cornea, brought about by the caustic action of the drug. The physician who brought me the case stated that the solution had been instilled twice daily for three weeks and that the strength was 1 per cent.

As to the proper time for making the applications of the silver-salt, it is my custom not to apply it early, before there is free secretion of pus, but to wait until the latter has fully established itself and the conjunctiva has become somewhat soft. The applications should be made daily, and immediately after a strong solution has been used cold compresses should be employed for a few minutes to reduce the inflammatory reaction which may result.

If at any time the cornea should become in the least degree hazy, a drop or two of a solution of atropin, gr. iv–f℥j, must be instilled at once and continued twice or thrice daily, and, as stated before, hot compresses must be used, these seemingly having a decided advantage over the cold in such cases. Should an ulcer form and threaten to perforate, it is perhaps better to anticipate nature by performing paracentesis of the anterior chamber and to keep it open for a few days, thereby assisting in the reparative process by the reduction of intraocular tension; and, no matter how severe the corneal complication should become, the vigorous and careful treatment of the conjunctiva should be carried on just as if it were not present.

By following carefully some such plan of treatment the vast majority of cases, if seen before any corneal involvement has taken place, can be readily cured, though, unfortunately, we sometimes see cases which, like the one of Randall,[1] through some peculiar influence that we cannot see or determine, and, in spite of all we can do to prevent, go from bad to worse, until the cornea ulcerates and the eye becomes practically lost. Knowing that such cases do exist, we should be careful to protect ourselves and our colleagues by being guarded as to any exact prognosis, no matter how simple a case may seem to be.

The necessity for being so careful in the prophylaxis of this affection is very well shown by the fact that carefully compiled statistics[2] show that in Spain and Belgium 12 per cent. of all cases of blindness are caused by this disease; in Switzerland, 26 per cent.; in the United Kingdom, 30 per cent.; in Germany and Austria, 33 per cent.; in the United States more than 32 per cent.

It has also been shown that more than 70 per cent. of all cases of blindness occurring in the first year of life are attributable to this disease, and that in nearly 9 per cent. of all births in which no preventive methods are employed ophthalmia results. These facts being considered, there should be no hesitation in employing every known and available precaution to prevent the disease.

The last census of the United States shows the total number of blind to be 50,411. If we take 32 per cent. of these, the number estimated to be due to ophthalmia neonatorum, we have in round numbers 16,131 whose miserable and most pitiable, as well as almost helpless, condition was brought about by this disease, the large majority of which might have been prevented had the prophylactic treatment been employed. By consulting the census records[1] from 1850 to 1890 we find the following statistics for the State of Pennsylvania:

---

[1] Journal American Medical Association, November 25, 1893.

[2] de Schweinitz: Annals of Gynecology and Pediatry, January, 1892.

Year.	Population.	No. of Blind.
1850,	2,311,786	829
1860,	2,906,215	1187
1870,	3,521,951	1767
1880,	4,282,891	3884
1890,	5,258,014	3925

The number of blind to each 1,000,000 of population in each of these periods is as follows: In 1850, 358; 1860, 408; 1870, 501; 1880, 905; 1890, 765. Thus it will be seen that the proportion of blind has steadily increased during each decade except the last; and, as I can learn of no method of enumeration for our State such as Dr. Bettman refers to for the State of Illinois[2] that would have materially increased the number in 1880, I am obliged to think that the proportion of infants affected by this disease is on the decrease, and that it is owing to the greater stress which has been given the subject in our medical schools during this last decade, to the number of papers that have been written calling the attention of the general physician to the disease, to the increased employment of antiseptic midwifery, and to the general and active discussion in many of our medical organizations throughout the country which, in many of our States, has resulted in legislation that, in a few words, makes it a misdemeanor, punishable by fine or imprisonment, or both, for any nurse or attendant upon a case of labor not to report to some reputable physician, or to the Public Health Officer, if either or both eyes of the infant should become in the least red or inflamed at any time within two weeks after birth. As is well known, if the case is seen early and proper treatment instituted, the result will almost always be a cure with perfect vision, though, as stated, there are some cases, malignant from the beginning, that go from bad to worse, despite all our efforts to the contrary.

It is hoped that we shall soon have such a law in our own State. The matter was brought to the attention of our State Medical Society at its last meeting by Dr. Gould, and a committee was appointed to use all means to have some such legislation as that indicated effected at the next meeting of our legislative bodies. Such a bill has been framed, is receiving the indorsement of medical societies, and I trust will have the support of every physician in the State.

1720 Arch Street.

FURTHER CONSIDERATIONS ON THE INFLUENCE OF OLD AGE IN SURGERY.

By N. F. GRAHAM, M.D.,
OF WASHINGTON, D. C.,
PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF HOWARD UNIVERSITY.

Judging from the recent literature on the subject, it may reasonably be inferred that more interest is manifested and greater trust placed in the recuperative powers of the aged than was formerly the case. The number of recorded cases of recovery from grave injuries and severe operations is fast placing the chances of old people, when in need of surgical aid, in a more hopeful light. The plea of old age as a bar to operation has, in times past, been so urgently insisted on by the friends and family of the patient that the surgeon has too often acquiesced, and permitted the opportunity to render the necessary assistance to escape him.

The number of persons requiring surgical operations when well advanced in years, above the age of seventy, for instance, is more numerous than the casual observer would suppose. The lessened activity, loss of muscular power, and the inability to walk firmly after this period render them more liable to falls, resulting in fractures, bruises, and lacerations, than is the case during the more active period of life. Then, too, the bones are more brittle, requiring less force to produce fractures than in the stronger bones of the young adult.

The absorptive and degenerative changes that take place in the soft as well as in the hard tissues of the body as age advances would seem, from a physiologic point of view, to discourage the idea that grave operations and injuries could be so successfully recovered from. Clinical experience, however, seems to be very fairly on the road toward establishing the propriety and even the necessity of operations in the aged, when demanded. The number of cases reported during the past ten or twelve years should encourage us in performing necessary operations in this class of cases, and in forgetting the plea of "old age," which has in former years been so successfully urged, often, I believe, to the detriment of the patient. Old people have been too often unfairly treated by surgeons, especially with respect to fractures. They have been allowed to go without suitable care, yet many have recovered with union, generally with deformity, when proper and skilful treatment would have given perfect or, at least, useful limbs, and some comfort in their declining years. Certainly a bone that will unite with the disadvantage of no adjustment will become repaired with greater certainty and more quickly if properly adjusted and splinted. Modern splints can be so neatly and snugly applied, particularly to the long bones, as to enable the nurse to handle the patient and relieve him from the discomfort of remaining constantly in one position, which has always been regarded as the chief difficulty in the management of fractures in the aged. The freedom of movement now obtainable prevents passive congestion, which is so common in all feeble persons. A well-adjusted plaster splint, which can be applied to the fracture a few days after the accident, enables the nurse or attendant to move the patient from side to side. When the break is below the knee the patient can be moved into an easy chair during part of the day, and even if the fracture be in the shaft of the femur he may, at least, be propped up in bed. In fractures of the arms, if the patient be strong enough, he may move about freely.

---

[1] After the manner of Bettman for the State of Illinois: Journal American Medical Association, May 19, 1894.

[2] Dr. Bettman quotes from the report of the State Board of Public Charities for Illinois that, in addition to the regular census-returns for 1880, there was private correspondence with physicians, who added many names to the lists. This was not repeated in the last census.

Those who live to the age of seventy years and over have not, as a rule, the senile changes so marked as those who die at or about that age. The heart and bloodvessels in the very aged are generally in comparatively good condition. The brain and entire nervous system, as well as the special senses, remain fairly good. That certain atrophic and degenerative changes take place in all old people, which impair all the functions of the body, is plain to the most superficial observer. Bones become brittle, glands are lessened in size, fatty changes take place, calcareous deposits are found in various parts of the body, notably in the heart and bloodvessels, but these changes are not present in the same degree in all. In some the changes are very marked, in others moderately so. The former, of course, do not stand operations so well, owing to their inability to recover from the shock, which is the chief factor of danger in injuries to or operations upon the aged. The more marked the senile changes the more danger from shock.

It is a matter of general observation that old people while suffering from diseases or injuries or recovering from operations complain less of acute pain than do younger persons. This may be accounted for by the fact that certain changes have taken place in their nervous systems which tend to make sensation less acute. They are thus saved from fretting, a fact that facilitates recovery. Nervous affections of any kind are not usual complications in the aged, and acute inflammatory troubles are not to be apprehended. It is rare also that they suffer from secondary hemorrhage. The chief points to be considered by the surgeon in making a favorable prognosis are a condition of fair general health, an hereditary tendency to long life, and the absence of very marked senile changes in the heart and bloodvessels.

Coincident with the senile changes found in the bodies of all old persons in a more or less marked degree it is found that the cells, though diminished in size, retain their physiologic characteristics, and respond to the demands made upon them for the repair of an injury or wound as certainly as in the young, though usually more slowly. This faculty in the cells to undergo all the changes necessary to repair a wound or injury accounts for the many good results following operations on old people.

The following cases, which have come under my observation since 1891, the date of my paper on "Old Age as a Factor in Surgery,"[1] may be of interest:

CASE I.—J. W., aged seventy-six years, came under my observation at the Freedmen's Hospital in the spring of 1891, suffering from epithelioma of the penis, which had destroyed the prepuce and the greater portion of the glans, and extended along the dorsum and left side of the organ to about its middle. I amputated the penis an inch from the pubes, leaving the urethra long, splitting it and stitching the two halves to the skin above and below. The location of the wound necessitated daily dressing. The wound healed partly by first intention and partly by granulation, and the patient was discharged from the hospital in five weeks, though he was comfortable and able to be about the ward and grounds after the second week. There has been no return of the disease.

CASE II.—M. S., aged eighty-four years, came under my care in June, 1891, with a strangulated hernia. Careful taxis was tried, with the aid of ether, cold and heat and position, without success. The man suffered much from nausea and vomiting, and was greatly depressed. Herniotomy was performed, with the result of what seemed at the time to be a radical cure. Two years afterward a protrusion appeared, which was controlled by a truss. Recovery in this case was slow but satisfactory. The patient was confined to bed for five weeks, after which time he was able to be up and about, and regained his usual activity. He had been a robust man all his life, and had never before suffered from any serious illness.

CASE III.—J P. was eighty-six years of age. In December, 1891, while making his way about a dark room, he tripped and fell, fracturing the neck of the right femur within the capsule. The condition was easily made out, as the man was very spare. The displacement was but slight, and the shortening less than an inch. The treatment was by sand-bags to the outer and inner sides of the limb, and a weight to the foot. The weight appeared to be so uncomfortable that it was removed in a few days. After six weeks in bed it was found that union had not taken place. After ten weeks he began to move around on crutches, and was able to do so until he died of old age, in the spring of 1894. He recovered entirely from the shock and the injury, and, although the bone failed to unite, he suffered no pain or discomfort after the first few days.

---

[1] MEDICAL NEWS, February 1, 1891.

CASE IV.—Mrs. J., seventy-nine years of age, sustained a fracture of both bones of the right forearm, the result of a fall down-stairs. When called to see her, two hours after the injury, I found her suffering from shock. She was severely bruised about the right side and shoulder, in addition to the fracture. I administered stimulants and adjusted the fracture, applying two well-padded straight splints. She suffered but little pain after the first forty-eight hours. At the end of three weeks the wooden splints were replaced by a plaster dressing, which was allowed to remain for four weeks longer. The bones were then found firmly united in good position, and she had perfect use of the arm and hand.

CASE V.—D. H., aged seventy-nine years, while standing on the end of a packing-box, four feet high, lost his balance and fell to the ground, striking his left shoulder on a peg driven into the ground. The wooden pin penetrated the soft parts and opened the shoulder-joint, synovial fluid escaping freely. The opening was at the inner edge of the deltoid muscle. The man being very spare, a portion of the head of the humerus could be brought into view at the bottom of the wound. The patient suffered from the concussion of the fall, but rallied within two hours. In the meantime I had closed the wound and adjacent parts after thorough cleansing with sterilized water only. There was but little bleeding. I placed a deep stitch in the middle of the wound, including all the tissues to the depth of the torn capsular ligament, and taking in enough of the thickness of the ligament to insure bringing it together without leaving any of the thread in the joint. This single suture brought the slit, which was an inch-and-a-quarter long, quite neatly together. Two additional stitches securely closed the wound. The man recovered without an untoward symptom, and was at no time confined to his bed an entire day. There was no inflammation or suppuration, and the wound was fairly healed when the stitches were removed on the twelfth day. The joint was kept immovable for four weeks, when it was found that, although somewhat stiff, there was fair mobility, which increased from day to day, until at the end of ten weeks the arm was as good as ever.

CASE VI.—In February, 1892, Mr. E., aged eighty-three years, fractured the neck of the left femur as the result of a fall in the street. There was no particular shock. He was treated by sand-bags and a weight to the foot. As is so often the case, the discomfort of the weight was so great that it was removed in a few days. The limb shortened a little over an inch. He was kept in bed for eight weeks, when it was found that there was good union. Being an active man he was allowed to go about on crutches. This he did for some months, when he abandoned them, and now uses only a cane. Though he has a perceptible limp, he walks well and is in good health.

CASE VII.—W. G., aged seventy-nine years, came under my care in January, 1892, suffering from severe concussion of the brain and spine. He had been struck by a rapidly moving coasting sled, which threw him with great violence to the frozen ground. He was picked up in an unconscious condition. Two ribs were broken, and blood flowed from the nose and ears. I believe there was fracture of the skull without depression. He recovered consciousness in twelve hours, but the intellect was confused and dull for a number of days. The ribs united without difficulty in six weeks, and he so far recovered from the injury to the brain and spine as to be able to resume his work as a clerk in about three months. He died in May, 1894, of cholera morbus.

CASE VIII.—Mrs. J. G., aged eighty-three years, had suffered for eight years from scrofuloderma of both feet and legs, extending to the knees. In August, 1894, she got out of bed, after midnight, for the purpose of getting a drink of water. She was seized with vertigo and fell backward, striking her head against a sharp, projecting hinge-pin, which entered the scalp just above the occipital protuberance, causing a severe laceration. The cut extended over the occipital bone, ending at the middle of the junction of the parietal bones, and making a ragged, comparatively straight cut over four inches in length. At the same time the scalp on each side of the cut was completely separated from the skull in an elliptical shape, the greatest diameter of which was over four inches. There were considerable loss of blood and marked shock, from which it took her twelve hours to rally. The wound was cleansed and sutured, and a dry dressing applied. The wound healed entirely by first intention, without soreness or evidence of pus. The stitches were removed on the eleventh day, when it was found that union was good, so that no further support was required. The result was the more remarkable in that the woman was a confirmed victim of the opium-habit, besides suffering from the tubercular affection of the legs.

CASE IX.—Mrs. W., aged seventy years, came under my care in the winter of 1893, for a fracture of the right humerus, near the shoulder-joint, due to a fall from a carriage. The fracture was adjusted, and the arm placed in two felt-splints. The outer splint covered the top of the shoulder. She was not confined to bed at any time, and union was complete in seven weeks. The shoulder was stiff for some time, but she eventually recovered full use of the joint. There was no deformity.

CASE X.—In June, 1894, Mrs. M., aged seventy-three years, called my attention to a hard, slowly growing mass in the left breast, which I diagnosticated as carcinomatous. When she first noticed the growth it was painless, but later she suffered from lancinating pains, and the tumor made very perceptible growth from June to October, when I advised its removal, to which she readily assented. On November 21, 1894, I extirpated the breast and neighboring glands. She sat up on the third day. The dressing was removed for the first time on the tenth day, when the stitches were also taken out. The wound was found to be well healed. On the thirteenth day after operation she walked a block to my office. In this case the repair was as rapid and satisfactory as it could possibly have been in a young and robust person.

In operating on old people I believe a great advantage is gained in preventing shock by keeping the temperature of the operating-room high, so that the extremities and the field of operation are kept warm.

CASES OF POTT'S DISEASE OF THE SPINE PRESENTING SOME UNUSUAL NERVOUS SYMPTOMS.[1]

BY LE ROY W. HUBBARD, A.M., M.D.,
OF NEW YORK.

THE ordinary nervous symptoms associated with spondylitis are so common that they do not merit more than passing attention. The pain in the back, chest, or abdomen, the peculiar respiration, the reflex muscular spasm, the weakness of the lower extremities, which may be followed by paraplegia and loss of power over the sphincters, are all symptoms and complications familiar to those who have seen many cases of Pott's disease. These nervous phenomena are quite easily explained by the pathologic conditions present, *e. g.*, the pain and muscular spasm, by irritation of the spinal nerves at their roots from pressure or inflammation, and the paraplegia by a pressure-myelitis. But occasionally symptoms arise out of the usual run that are not so easily explained.

Two such cases having come under my observation, I made a careful search of periodic literature for reports of similar ones, with the result of finding four that seemed to be remarkable and worthy of abstracting.

Two were reported in the *Glasgow Medical Journal* for 1886 by Gemmell, one occurring in his service at the Glasgow Hospital, and the other in the service of Dr. Middleton, who succeeded him. It is quite worthy of note that two such unusual and interesting cases should occur in the same hospital and within a few months of each other.

The first was in a child four years of age, who was sent to the hospital November 11, 1884, to be treated for "wry neck." On her admission a deformity of the upper dorsal vertebræ was observed. She was placed in bed and kept there, but no apparatus was applied. She remained in about the same condition as when she was admitted, and no unusual symptoms developed until June 26, 1885, seven months later, when she was seized with a violent paroxysm of dyspnea. The symptoms were so urgent that it was thought a foreign body had lodged in the larynx; but a careful examination by sight and touch failed to reveal its presence. Ether was administered and poultices applied to the neck. Gradually the distressing symptoms passed away, but the breathing never became natural, and she had subsequent attacks of dyspnea, though not so severe as the first one. At no time was there any difficulty in swallowing or paralysis of the larynx.

On July 12th the patient died, apparently from asthenia. The autopsy showed that the lungs, heart, and trachea were perfectly healthy. There was an abscess at the site of the third, fourth, and fifth dorsal vertebræ, containing considerable pus, but it did not project forward. There was no evidence of inflammation around the abscess, and the cord showed no material change in structure.

The second case, in a child of three years, was brought to the same hospital for "bronchitis" June 30, 1885. According to the history, the child had been feeling ill since the previous March, when he began to hang his head toward the left shoulder, and at the same time the "bend in the neck was discovered."

The pulmonary symptoms had appeared six weeks before admission, and it was reported that on several occasions he had been "choked up."

This child was also placed in bed, with no support, and nothing special was noted until early in September, when the breathing became croupy. Steaming and hot poultices were employed, with relief. On September 12th he had a more severe attack, which was again relieved by external applications; but on September 17th the dyspnea was so great that tracheotomy was performed. The child lived about one minute after the trachea was opened. In this case also there had been no difficulty in swallowing and no paralysis.

The autopsy showed a prevertebral abscess of the third, fourth, and fifth dorsal vertebræ. There was some compression of the cord, but no definite lesion.

I desire to call particular attention to the fact that both of these cases were treated without apparatus to fix the spine or support the head. The only treatment was the recumbent position, which, in a child of three or four years of age, amounts to no treatment. In the reports of these cases no attempt was made to explain the symptoms which had been present.

Faucon and Lavarand, of Lille, report a case in the *Lille Journal* for August, 1892, of a girl with disease high up in the cervical region, who had asphyctic seizures daily to the point of cyanosis. They applied a plaster jacket with a jury-mast, which relieved the symptoms at once, and the patient ultimately was cured.

A peculiar case of somewhat different character is reported by Hun in THE MEDICAL NEWS, vol. liii, page 90. An adult, thirty-four years of age, with Pott's disease located in the second, third, and fourth dorsal vertebræ, developed paraplegia. Exaggerated tendon-reflexes and ankle-clonus were present, with no loss of sensation in the lower limbs, while in the upper extremities there were symptoms of locomotor ataxia. The anesthesia, analgesia, and inability to coördinate the muscles were well marked and progressive. Unfortunately, this patient moved away, and the subsequent history was not obtained.

---

[1] Read before the Orthopedic Section of the New York Academy of Medicine, November 16, 1894.

The following cases came under my own observation:

P. S., twenty-eight years of age, a farmer, came to the New York Orthopedic Dispensary and Hospital, November 2, 1883. He had always been in good health up to one year before, and his family history was good, being free from all tuberculous taint. About one year previous to presenting himself he had quite a severe fall, striking upon his back. After a time he recovered sufficiently to perform his usual duties on the farm, but the back "never felt quite right." In the following June he attempted to lift a heavy hay-rack off a wagon, and strained his back severely. From that time he had more pain, so that it was difficult for him to ride or do hard work. In August he again lifted and strained the back, but not so severely as before. Within a few days he was attacked with violent pain in the back, shooting downward and forward along the course of the ureters and extending into the testicles. The pain was accompanied by scanty urine, and on several occasions hematuria was present. He was confined to the bed, and his symptoms so strongly resembled renal colic that he was treated for that trouble; but a careful examination of the urine failed to reveal any deposit or calculus. Six weeks of rest in the recumbent position so relieved him that he was able to get up. Soon the pain returned, not so severely as before, but of the same character, radiating down into the testicles. The hematuria did not return. He learned to hold himself in such a position that there was as little motion of the spine as possible, but was unable to continue his work. About this time he was seen by my friend, Dr. Egbert Le Fevre, and advised to come to New York for treatment. The examination of the patient showed rigidity of the spine in the lumbar region, with slight projection of the third vertebra. A diagnosis of Pott's disease was made and a Taylor spinal support was applied. This gave immediate relief, and he was comfortable as long as the support fitted properly. When it needed adjustment the pain in the testicle would return. The peculiar nervous symptoms in this case were the unusual location of the pain, the scanty urine, and the hematuria.

After wearing the brace for three years it was removed, and he has remained well ever since, doing the hard work on a farm.

J. F., thirty-one years of age, employed in a large machine-works, had always been in good health until February, 1890. On the 22d of that month he was assisting in the operation of lifting a heavy casting on top of a boiler. He slipped and fell, striking his back on the rounded surface of the boiler, and part of the weight of the casting fell across his pelvis. He fainted at the time, but upon recovery from that was able to be taken to his home, walking part of the way with assistance. He remained in bed for three weeks, and was treated for severe contusions. At the end of that period he was able to get up and went to the works, but did little more than to sit in a chair and direct the men. Three months after the injury both testicles became swollen and painful without cause. The left one was the worse, and finally suppurated, discharging considerable pus. A slight discharge continued for six months, and the swelling did not disappear for a year. He wore a suspensory-bandage, but was not confined to the bed. During this period he suffered from pain in the back, and if he made a misstep, or if any one seized him by the shoulder so as to give him a twist, it would bring on pain severe enough to cause him to faint. He consulted a number of physicians, and for nearly a year before I saw him had been treated at one of the large city hospitals for lumbago. In October, 1893, he began to have attacks of dyspnea, resembling spasmodic asthma. These came on at night, and were so severe that he was deprived of sleep, and was often obliged to sit up all night. The breathing became labored, even in the daytime, and soon a marked hoarseness appeared. As a result of this loss of sleep and worry he became emaciated and was very miserable. The ordinary remedies for asthma were tried faithfully by his physician without any benefit, and he was brought to my friend, Dr. Le Fevre, for consultation. The peculiarity of the breathing, and the absence of the usual signs of asthma, directed the attention to the upper air-passages. There was no history of obstruction or paralysis in the larynx; so he suspected a reflex cause. An examination of the back revealed a projection in the lumbar region, and the case was referred to me for treatment. The signs of lumbar Pott's disease were well marked, and I applied a Taylor support, supplemented by a strong corset. This gave him great relief, and after its application he had only one asthmatic attack. The breathing became easier, the hoarseness disappeared, and his general health improved. When I presented him to the Section in February he had gained thirty pounds, and was doing his ordinary work.

Though cautioned to be very careful about lifting, and advised to be regular in attendance, to keep the brace properly adjusted, he felt so much better that he became careless. He frequently lifted heavy weights, indulged somewhat in dissipation, in consequence of which he received a severe fall, and became irregular in his attendance. The result was that he came to see me in April with the report that he was nearly as bad as before. There was a slight increase in the kyphosis. After adjusting the brace I sent him into the country, where he could rest, and the result was that in a few weeks he was much better. I saw him during the latter part of the summer, when he was at work again. He promised to do no lifting and to be careful of his habits, and, as I have not heard from him since, assume he must be in fair condition.

That his asthmatic seizures, dyspnea, and hoarseness were dependent upon the spinal lesion seems evident from the fact that they were not like true asthma, that they improved at once under efficient support to the spine, returned again when the back was neglected, and again disappeared under rest and support.

The explanation of these cases is, of course, largely theoretic. We have a definite and well-known pathologic lesion, but with it symptoms out of the usual run which cannot be explained as a direct consequence of the lesion. The epigastric pain, the paraplegia, and other nervous symptoms have their explanation in the lesion. My own belief is that we must look to the sympathetic system, and regard them as reflex phenomena. Just why a certain number of cases, the disease being located in different regions, should be affected in this way, it is impossible to say. But it is no more strange than that a certain number of pregnant women should suffer from uncontrollable vomiting, while others pass through the whole period with no disturbance of the digestive organs. In certain people a slight attack of indigestion will bring on a severe attack of asthma, and some women are warned that conception has taken place by a peculiar hoarseness which comes on much earlier than the usual signs of pregnancy.

In those cases in which an autopsy was made there appeared to be no change in the cord. It is probable, therefore, that the source of irritation was at the roots of the spinal nerves.

Although the explanation of the symptoms occurring in the cases I have described may be theoretic, there are two practical points that may be learned from them. The first is that it is possible to have peculiar symptoms dependent upon a lesion of the spinal column, and the true nature of the trouble can easily be overlooked. The second is the importance of an early and efficient support to the spine as soon as the diagnosis is made.

326 Lenox Avenue.

FRACTURE OF THE LARYNX, WITH REPORT OF A CASE.[1]

By THOMAS J. HARRIS, M.D.,
OF NEW YORK,
ASSISTANT SURGEON MANHATTAN EYE AND EAR HOSPITAL; INSTRUCTOR ON DISEASES OF THE THROAT, NEW YORK POST-GRADUATE SCHOOL AND HOSPITAL; FELLOW OF THE ACADEMY OF MEDICINE.

The following case is reported because the condition is exceedingly rare and the cause in this instance is very unique.

Up to 1866 little or nothing was known about fracture of the larynx. At that time Hunt was able to collect only twenty-nine cases. Two years later Henecque reported fifty-two more. A careful examination of the files since Durham, in 1881, wrote his paper and brought the number of reported cases up to sixty-two, has enabled me to add thirty more, including the present case.

These thirty cases, together with accompanying data as regards the reporter, cause, symptoms, treatment, and result, are given in table on opposite page.

Strange as it may seem, in the face of these statistics, Lane, of London, in 1885, in a classic paper, showed, in 100 cases examined in the autopsy-room, 9 per cent. of fractures of the larynx.

Causes. The causes of fracture of the larynx are most numerous and varied. While they are in most cases direct, there are a number of cases reported by von Hoffman, of Vienna, in which the cause was entirely indirect. In 43 cases reported by Guert, 14 were caused by strangling, 8 by blows on the neck, and by some foreign body striking the neck.

Symptoms. The symptoms are very characteristic—pain, aphonia, and dysphagia, and in all the well-defined cases dyspnea, bloody expectoration, and emphysema. The dyspnea and emphysema are generally excessive, the latter sometimes involving the entire body. Crepitus and deformity are not constant, probably on account of the emphysema present. When a view of the larynx could be obtained with the mirror, the false bands were reported to be swollen to an excessive degree, causing virtual stenosis of the glottis. Cough is also a common accompanying symptom.

Prognosis.—Fracture of the larynx has always been regarded as a very fatal disorder.

In Durham's 62 cases there was a mortality of 88 per cent.; Albert found a mortality of 80 per cent.; Fisher, in 71 cases, a mortality of 78 per cent.; and Guert in 68 cases, 70 per cent.

Fractures of the thyroid are most common, and are regarded as most favorable for recovery. All authorities in the past have agreed that fractures of the cricoid are without exception fatal.

In the 30 cases collected in this paper the statistics are much more favorable. The total death-rate was only 30 per cent. for fractures of all kinds. Still more encouraging is the fact that in the 30 cases there are 5 cases of fracture of the cricoid, with recovery in 4, or 80 per cent., and 5 cases of multiple fracture (thyroid and cricoid), with recovery in 2, or 40 per cent. The remaining 20 cases consisted of 19 cases of fracture of the thyroid, with recovery in 80 per cent., and one case of fracture of the hyoid resulting in death.

These results are in direct correspondence with the assertion of Lane, who insists that the death-rate has been greatly over-estimated.

Among these 30 cases, instead of the clinical picture of great dyspnea and emphysema, there are, including the present case, 6 cases in which the patient presented himself for some resulting disorder a considerable time afterward, one reported by Morgenthau, 3 weeks later, for hoarseness; Barling's case, 6 days later, for hoarseness; Masucci's 8 days later, and two cases reported by Sajous, in

which the injury occurred some time previously, and the only complaints were those of the laryngitis. It is hard to reconcile this great variance in the severity of the symptoms unless it is, as Sajous suggests, that in these cases, with such slight disorder attendant, the fracture was incomplete, and that when only the upper part of the thyroid is involved and the lower part spared violent symptoms will be absent, and radical interference is uncalled for.

Treatment. As regards treatment, Hunt asserts that he has never heard of a case in which emphysema and bloody sputum were present in which recovery took place without tracheotomy. All authorities advise tracheotomy when urgent symptoms exist. Recently the opening of the larynx and coaptation of the fragments have been suggested, also the introduction of O'Dwyer's tube. The statistics in the 30 cases studied are, accordingly, of interest in this relation. Of the 30, tracheotomy or laryngotomy was practised in 11, or in 36 per cent. In 19, or 64 per cent., it was not performed. In the 11 cases in which tracheotomy was practised death resulted in 2, or 18 per cent. In the 19 cases in which tracheotomy was not practised death resulted in 7, or 30 per cent. In the latter list there are 11 cases of thyroid fracture, with only 2 deaths, or but 18 per cent., and 3 cases of fracture of the cricoid, with death in 1 case, or 33 per cent.

The history of the present case is interesting, in reference both to its etiology and its course. Briefly it is as follows:

O. H., aged forty-four years, a musician by profession, was a member of the United States Band at West Point. All evidences or history of constitutional disease are lacking. The man states that for some time previous to the accident he had been compelled to play eleven different musical instruments. Three years ago, in October, while playing the baritone, an instrument akin to the trombone, he suddenly felt a pain in the right side of his neck, which was accompanied by a great amount of swelling, extending to the right ear. Coincidently there were loss of voice and dysphagia. At the same time he detected much pliability in the bones in his neck. Dyspnea resulted at once. The patient was never deaf previous to this accident; but since then there has at times been a discharge from both ears, especially the left, with great deafness. Two months later headaches began, which have been persistent and very distressing ever since. Cough has been a persistent symptom. The swelling continued for over a year, gradually subsiding. The patient was referred to me by my friend Dr. Reynolds, United States Army, and I saw him for the first time one year ago this present month.

During the past year the condition has in no essential particular changed. The man's chief complaint is from the severe persistent headaches, situated chiefly in the occipital region, and aggravated by pressure on the larynx. Since the accident dyspnea has persisted, and no later than last night, he states, his wife was alarmed on account of his great difficulty in breathing. There has been an almost total inability to swallow solids. The larynx also is painful at times.

Examination externally shows an excessive amount of mobility of the thyroid. Although not absent, the pomum Adami is not clearly defined. Immediately on grasping the thyroid the patient experiences pain on the right side.

The fingers pushed under the right ala at its upper border can detect a distinct crepitus when the patient swallows, while he states that he feels a marked rubbing of the two bones in the act. Pain is also produced when the cornu of the hyoid bone on the right side is grasped. Examination of the larynx with the mirror reveals nothing beyond signs of a chronic inflammation, although the false bands have always been rather acutely swollen. Examination of the left ear gives:

Watch . . .	= 0	a.c ; b ċ. M. T. sunken.
Tuning Fork . .	C	3/3
R . .	C^{ii}	3/3
. .	C^{iii}	5/3
. .	C^{iv}	5/7

Although I have repeatedly examined the patient, I have never been certain how extensive was the injury. The most probable condition is one of fracture of the superior cornu of the thyroid on the right side, with loss of function of the right lateral thyro-hyoid ligament. Whether there has been any associated injury of the cornu of the hyoid, it is at this late date scarcely possible to determine definitely.

TEXAS TYPHOID OR THE SO-CALLED TYPHO-MALARIAL OR SLOW FEVER.

BY J. ESTILL MILLER, M.D.,
OF LOCKHART, TEXAS.

THERE has been a great deal of doubt whether the fever which has been raging in the southern portion of Texas is typho-malarial, typhoid, or a separate and distinct type, called by some "slow fever."

During this epidemic I have treated 46 cases of this fever, and have carefully noted the symptoms in every case from the beginning to the end. I shall endeavor in this article to give the history and symptoms of the fever, so that the reader may draw his own conclusions as to whether this is true enteric fever or a separate and distinct type of disease.

The disease often runs through an entire family, attacking successively one after another, rarely two at the same time. There is usually a short prodromal period of headache, and a feeling of malaise; in about one-half of the cases there is loss of appetite, whilst in another portion the appetite is preserved throughout the entire disease, the patient often becoming hard to control because of his great desire for food. There is always an indisposition to work. The tongue in the beginning has a mottled or freckled appearance along the anterior portion of the dorsum, with red margins, and often with a triangular red spot at the tip. The papillæ are slightly elevated; on the posterior portion of the dorsum there is a whitish-yellow, furrowed coat. Later in the disease the tongue often becomes dry, and is protruded with difficulty; the coat now becomes brown, or cleans off in flakes, leaving a bright-red surface.

There are always gurgling and tenderness in the right iliac region on pressure; borborygmi and obstipation are often present from the beginning. Thirty of my cases were constipated; the others began with a slight diarrhea. If the patient does not receive the proper diet and treatment, there will be tympanites and a low muttering delirium. The stools are dark and very offensive at first, gradually assuming the "pea-soup" characteristics.

Among the nervous phenomena are flushing of the cheeks, often one and then the other, and slight delirium, the patient declaring that he is freezing when the fever is the highest, etc. I saw one patient with Dr. Coopwood in which the teeth chattered and the patient could not control the lower jaw. The hands and feet are nearly always cold at some stage of the disease, and may remain so for days.

The pulse in the beginning is often dicrotic; otherwise there is no material change, except when the patient is very weak or there is hemorrhage. The frequency increases in proportion to the fever-height. The temperature has the characteristic typhoid curve, beginning low and gradually increasing, until between 103.5° and 105° in the evening and 101.5° and 103° in the morning is reached; this continues until the turning-point is reached, when it falls in the same curve. During convalescence there are slight exacerbations of temperature, finally leaving the patient entirely free from fever. In the beginning or first stage the fever is very hard to control, and can only be reduced after prolonged bathing, often requiring from thirty to sixty minutes' sponging in cold water; in fifteen minutes after discontinuing the bath temperature is at its former height. Quinin, except in antipyretic doses, has no beneficial effect upon this fever.

The spleen is always enlarged, and in some cases the liver also.

The duration of the disease is variable, running from thirteen to forty-five days; most of my cases continued from fifteen to twenty-one days.

This fever differs from typhoid in the absence of the rose-spots. I have examined carefully in every case, and I have *never* succeeded in finding these spots on any portion of the body or extremities at any period of the disease. Among the forty-six cases, I had one in which there was hemorrhage from the bowels. None had nose-bleed or perforation.

I had two cases in the same family, occurring simultaneously, one sister, eighteen years old, the other twenty. The latter pursued a typical course, except that during convalescence she had furunculosis. The former after two or three days' treatment seemed to recover, and, although I cautioned her to continue the treatment, she did not heed my warning, and in from ten to twelve days she was again attacked with the fever, which ran a very severe course, lasting twenty-seven days; during her convalescence she also had a skin-eruption, which resembled varicella.

My friend Dr. C. B. Coopwood was kind enough to furnish me with the following report, based on eighty-four cases treated by himself during the epidemic:

At no stage of the disease did he find the "rose-spots" on any of his patients, although he looked carefully for them. None of his cases had *nose-bleed;* five had hemorrhage from the bowels, two had perforation. In one of the latter cases he and Dr. Chambers held a post-mortem examination, with the following results: The Peyer's patches were found ulcerated opposite the insertion of the mesentery, with typical typhoid ulcers. In the bottom of two of these was found a slit-like perforation. The symptomatology in this case did not differ from that in the other eighty-three cases, except if anything it was a little milder.

The mortality is about the same as is laid down in most of our recent text-books as that of typhoid fever. Dr. Coopwood tells me that he lost five patients out of eighty-four, and I lost one out of forty-five cases.

Our treatment is about the same as recommended by Dr. Yeo at the International Medical Congress at Rome, minus the quinin. Such conditions as those I have outlined need no comment, and prove conclusively to my mind that the time-honored rose-spots and nose-bled are not the necessary accompaniments of true enteric or typhoid fever.

CLINICAL LECTURE.

PARALYSIS OF THE FACIAL NERVE; NEURALGIA OF SUPERIOR MAXILLARY NERVE.

[Clinic at the Buffalo General Hospital.]

By ROSWELL PARK, A.M., M.D.,
PROFESSOR OF SURGERY IN THE UNIVERSITY OF BUFFALO.

Here is a man who came to this city expecting to have a very severe operation performed. He returns without it, happier in mind and somewhat relieved in body. You may remember that in the last year I have twice removed the Gasserian ganglion to relieve intense facial neuralgia. From reading the report of one of these operations, an out-of-town physician sent me this patient. I expected to find a man haggard and worn by suffering, reduced in flesh, with the facial appearance of suffering, perhaps with spasm of the face. The patient, however, showed none of these appearances. He occasionally puts his hand to his face, not to relieve a paroxysm of pain, but to cover the right eye from the glare of the light, as it is exposed on account of a paralysis of the orbicularis. On asking him to show his teeth, only the left side of the mouth moves. The tongue is fairly well protruded, as it is only slightly affected. There is some complaint of pain, but not to the extent which I expected. He has a facial paralysis with a certain amount of referred pain due to exposure of branches of the fifth nerve, especially in the conjunctiva and cornea, because they are not protected from dust. This trouble came on by degrees about eighteen months ago.

The patient is a man, aged fifty-one years, a miner, apparently of steady habits. We can get no account of alcoholic excess or of syphilis. Even tobacco has been used very moderately.

Having decided that this is a case of facial paralysis, the next question is to find the lesion. There is a slight impediment to speech, and the voice wavers a little, as if there was some involvement of the glosso-pharyngeal nerve, as well as the seventh. Pain is felt also in the tongue. To explain the joint affection of these nerves we must remember that their nuclei are very close together at the base of the brain in the pons. If we can suppose a lesion that involves decidedly the origin of one nerve and extends somewhat to the origin of the other, we can explain the trouble very well. We cannot explain the symptoms as due to pressure or injury in their passage through the skull, for the nerves do not issue through the same foramen. The gradual development points to a slow degeneration of nerve-tissue. There is neither the constant headache nor the retinitis which indicates brain-tumor. There is no complaint of pain on manipulating the face nor on pressing over the exits of the supra-orbital, infra-orbital, and other branches of the fifth nerve; hence there is no reason for considering the trouble neuralgic. Without making a positive diagnosis, I believe the trouble to be some form of degeneration in the nerves, progressing outward from the nuclei.

There is no indication for operation. I have suggested that the eyelid be kept closed by a little piece of adhesive plaster, and have recommended faradization of the face to retain what little activity remains. If the condition be a true degeneration, there is not much hope of ultimate recovery; but I prefer giving the patient the benefit of the doubt, and keeping the muscles in as good tone as possible. Purely empirically, I have suggested the administration of potassium iodid.

In contrast with this case of paralysis, here is one of true neuralgia in a man of about the same age—fifty-five years. He is a hard-working man, a day-laborer, and he tells me that some months ago he had a tooth pulled which had been paining him. All the teeth are now gone from that side of his jaw, so that I cannot tell which tooth was the offender. However, on questioning him further, I learn that the same pain has persisted since the removal of the tooth, so that I question whether his trouble was not rather a neuralgia due to other cause than to ordinary dental caries. The pain is felt particularly in the jaw, but also over the side of the face below the eye. Thus, only the second division of the fifth nerve is affected. The pain goes around nearly to the ear, and is felt particularly over the antrum, so that I infer that the whole of the second division is affected, but that the trouble is more pronounced in the infra-orbital branch. Although the pain is constant, it is subject to exacerbations of the nature of tic douloureux. I have told the patient that the nerve affected may be removed entirely; that if the neuralgia be peripheral in origin, the cure will be complete. On the other hand, it is possible that the trouble is central in origin, and, in that case, the operation will not afford relief. The history of facial neuralgia shows that it may be operated upon again and again. One may read of cases in which the nerve has been divided at its exit from the mental foramen, then along the ramus of the jaw in the mouth, by Pancoast's operation, with relief for a year or two, and later a return of the trouble, so that the jaw has been resected and the nerve torn from its channel. Still later a more radical operation may have been necessary.

In this instance, I shall attack simply the infra-orbital nerve, which is very easily found. It comes out of the infra-orbital foramen along with the artery, a little vein entering at the same place. The foramen is nearly half-way between the two canthi. The incision is made longitudinally. Having found the nerve, I pull it out and divide it as far up as possible. The second division of the fifth nerve descends through the foramen ovale, comes out through the spheno-maxillary fossa, and then runs in the infra-orbital canal or trench. Sometimes the course of the nerve is almost within the orbit, sometimes more in the antrum. One never knows until the nerve is exposed just what course it takes. It is possible, however, to lift up the eye and chisel through the bony covering of the conduit, then pull out the nerve and divide it well back toward the spheno-maxillary fossa.

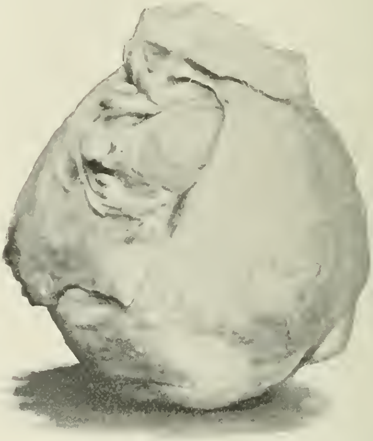
This man showed on the cheek over the infra-orbital foramen a scar. If it were not that this antedated by many years the beginning of his neuralgia, I should attribute the trouble to an entanglement of small branches of the nerve in the cicatricial tissue.

PATHOLOGIC NOTE.

A RARE DERMOID.

BY S C. GRAVES, M.D.,
OF GRAND RAPIDS, MICH.,
VISITING SURGEON TO THE U. B. A. HOSPITAL AND TO THE CHILDREN'S HOME.

THINKING that a cut and description of a very peculiar dermoid might prove a matter of interest to the readers of THE MEDICAL NEWS, I take pleasure in forwarding the same.



The peculiar feature of this tumor, as can be readily seen, is the very evident attempt on the part of a bit of sequestrated skin to form a portion of a human being. The left side of a human face is clearly intended.

The sequestration-theory of dermoid-genesis is the one, I believe, now generally accepted by investigators. At least Sutton, in his late work, *Tumors: Innocent and Malignant*, published October, 1893, announces this view. Tillmann's *Surgical Pathology*, published 1894, also accepts the same view.

The following is a description of the tumor by Dr. William Fuller, of this city, who has given the growth careful study:

In this dermoid cyst, there is developed a well-marked eye, with a molar tooth in the situation of the cornea. The palpebræ are distinctly developed, with cilia on the margins. The outer canthus is united, while the inner is incomplete, the internal extremity of each lid terminating in a cartilaginous prominence. Behind the eye is a roundish, irregular bone (sphenoid?), having a foramen (optic?) in the center, from which springs the apex of a fascia, conical in shape, the base expanding to receive the undeveloped globe of the eye. Above the eye are two triangular bones (frontal?) with a cleft between them (frontal suture?). These bones join together below in front and articulate with a bone (nasal?) which extends downward for one-half an inch, and is continued by a cartilage (nasal septum?), from the side of which springs a well-marked ala, enclosing a nostril about one-quarter of an inch in depth.

Below the nostril is an upper lip, having a well-marked dermoid appearance above and abruptly bounded by mucous membrane below. A mat of blond hair, mixed with dermoid matter (sebum), springs out of a depression above the frontal bone, while the eyelashes are black.

A white cord runs obliquely outward and upward along the lower margin of the frontal bone (or vital ligament?) Beneath and parallel to it is a streak of muscular tissue (levator palpebræ sup.). The cheek has the appearance of skin, with a few velvet hairs near the upper lip.

The Fallopian tube and broad ligament formed the pedicle of the tumor, the major part of which is a cyst that contained a greenish limpid fluid, of a salty taste, and is lined by a serous membrane. The cyst-wall is composed of two membranes with intervening cellular tissue. The bloodvessels of the cyst are long and delicate, indicating its rapid growth. The weight of the tumor is three pounds.

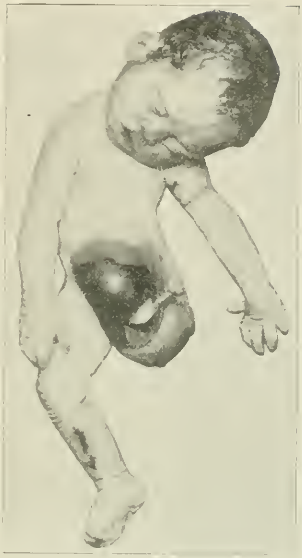
The tumor here described was obtained from a patient of Dr. J. O. Edie, a woman twenty-two years of age, married, who had one child, two years old, and who was operated on at the U. B. A. Hospital, November 12, 1894. The cast was prepared by Dr. William Fuller.

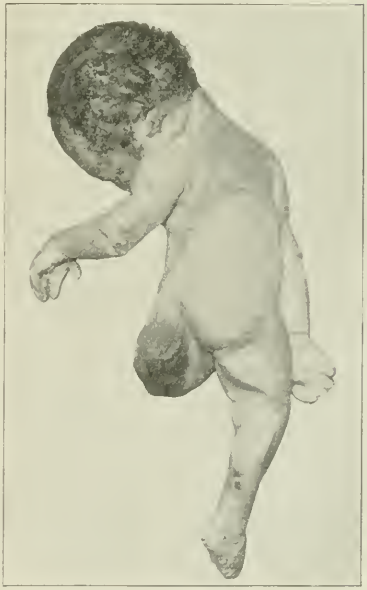
TERATOLOGIC NOTE.

A SPECIMEN OF DEFECTIVE DEVELOPMENT OF THE ABDOMINAL WALL AND EVENTRATION, CYLLOSOMA.

Presented to the Wistar Museum by Dr. I. Leopold, of Philadelphia.

Reported by B. C. HIRST, M.D.,
of Philadelphia,
Professor of Obstetrics in the University of Pennsylvania.





When defects of the abdominal wall are situated more to one side than another the corresponding lower limb is rudimentary or absent. The protrusion of abdominal contents, especially of the liver, on this side looks a little like the rudiment of the absent limb, as may be seen in the photographs, but a slight examination shows the true character of the tumor. The external genitals, the urethra, and the anus are commonly absent. In cyllosoma (Geoffroy Saint-Hilaire) the lateral eventration is on the left side in 72 per cent. of the cases (35 out of 48), and the vast majority of the infants are females.

The history of Dr. Leopold's patient accounts in no way for the deformity of the infant. The woman was a healthy primipara, twenty years of age, and there had been nothing noteworthy during pregnancy, except an occasional discharge of blood at the menstrual periods.

MEDICAL PROGRESS.

Excision of a Sub cortical Tumor of the Brain.—Beevor and Ballance (*British Medical Journal*, No. 1775, p. 5) have reported the case of a woman, thirty-nine years old, in which for twelve months there had been progressive loss of power in the right lower extremity, and for seven months also in the right upper extremity. Four or five weeks before coming under observation speech was for three or four days stuttering and thick, and for three weeks tactile sensations were not properly localized on the affected side, while light touches were not felt at all.

At the time that speech became affected there occurred an attack of vomiting, associated with severe headache referred to the frontal region. The vomiting had recurred intermittently. No history of a definite fit or of giddiness could be obtained. Double optic neuritis had been observed for three weeks, and for one week there had been attacks of sudden pain of a hammering character on the left side of the head. The patient was fairly well nourished. The face was expressionless, and the mental state dull. There were no delusions, but the memory was poor. The temperature was rather subnormal, but equal on both sides. The pulse was 100. The movements of the right side of the face, exclusive of the eyes, were less brisk and rather weaker than those of the left side. The upper facial muscles acted quickly, as did also the muscles of mastication, and the tongue was protruded straight.

In walking the right leg was swung forward. Wrist-tap and knee-jerk were increased upon the right side, and ankle-clonus was present. The muscular sense was lost in the right upper extremity and in the right toes and ankle. There was diminished sensibility upon the right side below the level of the face.

Treatment with mercuric chlorid and potassium iodid was instituted, but the symptoms failed to improve. Operation was, therefore, proposed and acceded to. A large flap, shaped like an inverted U, was made upon the left side of the head, including the periosteum, and allowing of exposure of the coronal and sagittal sutures, about one inch of the posterior part of the left frontal bone, and practically the whole of the parietal bone, with the exception of the anterior inferior angle, and the part immediately adjacent to the lambdoid suture. A parallel square-shaped portion of bone, whose anterior and posterior borders ran parallel with each other and with the sulcus of Rolando, was marked out by means of a saw. The upper border corresponded with the sagittal suture and extended along it from the bregma for fully three-and-one-half inches. The lower border was parallel with the upper and two-and-one-half inches below it. The area thus outlined was divided into small quadrangular pieces by vertical and horizontal cuts of the saw. These pieces were then easily raised from the dura by an elevator. As soon as one piece had been removed the use of strong bone-cutting forceps facilitated the final separation and removal of the pieces into which the bone had been mapped out. Along the upper boundary of the opening into the skull the final removal of the bone was accomplished in part by disintegration at the sagittal suture. In this way the dura was exposed without injury, and the middle meningeal artery lay upon it without having been wounded. The dura bulged considerably into the opening into the skull.

As it was decided to perform the operation in two stages, the edges of the scalp-wound were brought together by horse-hair sutures, an antiseptic dressing applied, and the patient put back to bed. Six days later, the patient, having recovered from the previous operation, was again anesthetized. The wound was found to have united by first intention, but its edges were easily separated by the handle of a knife after the stitches had been cut. The scalp-flap was again thrown down and wrapped in an antiseptic dressing. A small clot that lay upon the dura was removed, and as large a square dural flap as possible was cut and fastened down over the scalp-flap. The cortex thus exposed was bulging, and, especially over the upper part of the ascending parietal convolution, presented a mottled, unnatural appearance. On palpation no area of special resistance indicating the site of a tumor could be discovered, but on exploring the mottled ascending parietal convolution with the finger, the cortex, being here greatly thinned, was broken through, and a tumor of whitish-gray color was seen. As the ruptured cortex receded the tumor appeared to be discontinuous with the brain-substance, and an attempt was made to shell it out with the finger and the handle of a sterilized silver spoon. This was, however, impossible, as the growth was discovered to be continuous with and involving the surrounding cortex and also the substance of the hemisphere about an inch below the surface and toward the front and middle line. The tumor was semigelatinous in consistence and softer than the normal brain-substance, and it was found easier of removal with a silver spoon.

Considerable hemorrhage occurred, for the control of which a series of fine silk threads were passed through the cortex for a depth of about three-quarters of an inch all around the affected area, except for about an inch at the median line. This area was about two-and-a-quarter inches in diameter.

A free incision was then made through the cortex all around and just within the line of ligature, and all the included part, bone and tumor, was taken away by means of the spoon. The tumor extended to the medial surface of the hemisphere, and so a part of the marginal convolution and quadrate lobule was removed, the falx being equally exposed. In this way as much of the tumor as possible was removed, but as the line of junction of healthy and diseased tissue was so indeterminate, it could not with certainty be known if the whole tumor was excised. It, indeed, seemed probable that it was not.

At the close of the operation the brain presented a large cup-shaped cavity, nearly two inches deep, and the size of half an orange. It was thought that the area removed comprised the upper part of the ascending frontal and parietal convolutions, the anterior part of the parietal lobule and the adjacent portions of the marginal convolution. When all bleeding had ceased the dural flap was carefully stitched in position with fine silk. No bone was returned, but the scalp-flap was brought into place by many horsehair stitches. During the progress of the operation the brain-wound was constantly irrigated with 1 : 2000 solution of mercuric chlorid by squeezing a wet cotton wool mop over it.

The patient was kept warm by hot bottles. She was, however, much collapsed after the operation, and the temperature had fallen to 95°. After a brandy enema had been administered the bed was placed in front of a large fire, and fresh hot bottles were applied. Her condition improved, and the danger of death from shock soon passed away. On the day following the operation the pulse was improved, though still of poor force and tension. There were marked aphasia and complete paralysis of the right arm and leg. A day later there occurred a series of spasms, each lasting a few minutes, involving the right angle of the mouth. On the following day a similar attack, lasting three hours, took place, but after this convalescence was uninterrupted.

The dressings were changed twice on the second day after the operation, and again ten days later, when the stitches were removed. The improvement was progressive, and four months after the operation the hair had grown sufficiently to cover the area of operation. The scalp covering the opening in the skull, which had been a little concave, had reached the normal level. The edges of the bony opening were not quite so sharp as they had been. The scar itself was found with difficulty. The mental condition was restored to the normal; speech was perfect; there was no headache, and the movements of the face were normal. There was impairment of mobility in the extremities on the right side, with some rigidity in the upper, and deformity from muscular shortening in the lower. Sensibility in its various forms was normal. Upon histologic examination the growth was found to be a sarcoma with round and spindle-cells.

Successful Celiotomy for Perforated Gastric Ulcer.—ATHERTON (*Medical Record*, No. 1261, p. 2) has reported three cases of perforation in the sequence of gastric ulceration, in one of which death ensued without operation; in a second, death followed the making of a small opening in the epigastrium, with the evacuation of about two quarts of sour, greenish fluid from the peritoneal cavity, and the introduction of a drainage-tube; in the third, a successful issue was brought about by celiotomy and suture of the margins of the perforation.

The last case occurred in a woman, twenty years old, who, following a meal, was seized with intense pain in the left epigastrium and hypochondriac region, together with the vomiting of thin, sour fluid. The left upper abdomen was somewhat hard, tender, and slightly hyperresonant, but not noticeably distended. Hypodermic injection of morphin afforded temporary relief, but operation was deemed advisable. An incision between four and five inches long was made in the middle line of the epigastrium, and on entering the peritoneal cavity a few ounces of turbid serous fluid escaped, and the somewhat distended stomach presented. The viscus was somewhat adherent in the neighborhood of the pylorus. Here the peritoneal covering was red and thickened, and covered with shreds of lymph, which partly surrounded an opening about as large as a quill, near the gastrohepatic omentum and not far from the pylorus. Two sutures of fine silk were introduced, by means of a common sewing-needle, close to the margin of the opening, and tied, thus snugly closing the orifice. Outside of this five or six Lembert sutures of the same material were placed. Several times the thread cut through the soft, thickened peritoneal coat, but finally a sufficient number held the folds of the indurated walls of the stomach close together until all of the sutures were tied. The abdominal wound was closed with silkworm-gut sutures, washing of both the stomach and the peritoneal cavity and drainage being omitted. A dressing of iodoform-gauze was finally applied. During the operation the patient vomited a pint of greenish fluid.

The subsequent treatment consisted in the administration of hypodermic injections of morphin as required, the introduction of nutrient enemata, and teaspoonful-doses of cold water.

At the end of four weeks the patient was able to be about; and several days later was dismissed in good condition.

Hydatid Cyst of the Parotid in a Boy of Seven.—PIÉCHAUD (*Archives Cliniques de Bordeaux*, 1894, No. 11, p. 508) has reported the case of a boy, seven years old, who presented a swelling in the right parotid region as large as a small mandarin. This had first been noticed some eighteen months previously, and had slowly and gradually increased in size. There had been slight complaint of toothache, but there was no ulceration of the gums. As the swelling increased there occurred snoring at night and difficulty in swallowing. The tumor seemed to be a part of the inferior maxilla, and occasioned some displacement of its ascending ramus. On palpation the mass appeared to be a unilocular cyst, elongated vertically and included between the ascending limb of the inferior maxilla and the mastoid process of the temporal bone. On opening the mouth the swelling was found to invade the pharynx, displacing the tongue, the right pillars of the fauces and the tonsils to the left. With the finger in the mouth fluctuation could be detected, and the light of a candle placed near the tumor on the outside was transmitted to the interior of the mouth. By means of a syringe about two-and-one-half drams of fluid were carefully removed from the cyst. The fluid was alkaline, of a specific gravity of 1006, contained no albumin, but 5 per cent. of sodium chlorid, no cellular elements, no cholesterin, and no hooklets. This operation did not sensibly diminish the size of the swelling, although its tension appeared to be reduced. A second puncture, eight days later, evacuated more than two ounces of fluid, in which were found scolices with attached hooklets, and also free hooklets. The swelling was notably reduced, but for several days the fluid reaccumulated; finally, however, the swelling entirely disappeared. Recovery was interrupted by an intercurrent attack of measles, but was ultimately perfect.

Union of Fractured Clavicle by Suture.—ROUTIER (*Revue d'Orthopédie*, 1894, No. 6, p. 445) has reported the case of a woman, twenty years old, who sought relief for a deformity at the outer portion of the right clavicle of progressively increasing degree. It was learned that a week previously she had fallen from a carriage and fractured the clavicle at the junction of the outer third with the inner two-thirds. The outer extremity of the inner fragment appeared as a prominence beneath the skin, and by depressing the soft parts the surface of the fracture was reached. Below and behind this prominence the inner extremity of the outer fragment could be felt. The separation equalled two fingers' breadths. Fairly firm union had taken place and the deformity was quite considerable. It was proposed to attempt to correct the deformity under anesthesia, and should this fail to expose the bone and bring the fractured parts in accurate apposition. Permission having been obtained and simple reduction failing, the second procedure was carried out and the two fragments were sutured with strong silk. The overlying periosteum was carefully replaced and sutured with fine silk. The wound was closed and suitably dressed. In the course of three weeks firm union had taken place without the least deformity.

Inferior Bilateral Hemianopsia.—Adelheim (*Médecine Moderne*, 1894, No. 101, p. 1582) has reported the case of a man thirty-six years old, who presented loss of vision in the lower half of the field of vision of both eyes. His personal history was good, but his mother and sister had been epileptic, and the mother had lost her vision long before death. Shortly before coming under observation the patient had had some form of infectious disease, the precise nature of which could not be learned. In the course of a month he suddenly, on awaking one morning, noticed derangement of vision with the left eye. Objects appeared to be surrounded by a haze, and he was able to see only their upper half. Slight amelioration of this condition followed the application of leeches to the left temple, but six days later similar phenomena appeared upon the right side. On examination it was found that while most of the other functions of the eyes were normal, the lower half of the field of vision of both eyes was completely abolished. The left eye presented, besides, partial peripheral anopsia in the superior half of the visual field, in the temporal quadrant. Illumination of the superior portion of the retina induced a less active contraction of the pupil than illumination of the lower portion. On ophthalmoscopic examination the superior half was found to be distinctly paler than the lower half. No lesion of the nervous or visceral system could be detected. Varied treatment was without effect, and four years later the condition was found to be unchanged. But seventeen similar cases could be discovered in the literature.

A Remarkable Bullet-Wound.—At a recent meeting of the Royal Society of Physicians of Vienna, Zemann (*Wiener medizinische Blätter*, 1895, No. 51, p. 781) presented the spinal column and liver from a boy, fifteen years old, who died of septicemia nine months after attempted suicide by shooting. The bullet had passed through the left lobe of the liver and the body of the eleventh dorsal vertebra, and between the vena cava and the aorta, without injury to either of the latter. The original injury to the liver had entirely healed, but the projectile had gained entrance into the vertebral canal, causing compression of the cord.

THERAPEUTIC NOTES.

A Contribution to Organotherapy.—Shoemaker (*University Medical Magazine*, vol. vii, No. 5, p. 309) has reported the case of a woman, thirty years old, with symptoms of Addison's disease, in which improvement followed injections of a glycerin extract of suprarenal capsules of the beef. Fifteen minims of the extract represented ten grains of the capsule, and from twelve to twenty minims were injected at intervals of from one to three days for a period of two months. The most marked influence of the treatment was upon the weight, which increased from eighty-nine to one-hundred-and-seven pounds. When the injections were suspended, the weight decreased seven pounds during the following four weeks, remaining stationary for a month, and then steadily and progressively increasing.

Wood (*Ibidem*, p. 311), having observed a case of exophthalmic goiter in which the symptoms improved after the spontaneous evacuation of a splenic abscess, was led to administer a glycerin extract of beef spleen in another case of exophthalmic goiter, and with satisfactory results. The extract was injected beneath the skin daily, at first in doses of five minims, subsequently increased to ten minims.

The Active Principle of Rhus Toxicodendron and Rhus Venenata.—At the recent meeting of the American Physiological Society, Pfaff (*Science*, 1895, vol. i, No. 5, p. 119) reported the separation from rhus toxicodendron and rhus venenata of a non-volatile oil, which, when applied to the skin, caused typical dermatitis venenata. The general opinion hitherto has been that this skin-eruption was dependent upon the action of a volatile proximate principle, and toxicodendric acid has been generally accepted as the active poison. For prophylaxis, thorough washing with an alcoholic solution of lead acetate was proposed. The oil is soluble in alcohol, and forms a nearly insoluble lead-compound in alcohol, and is thus best removed from the superficial skin.

The Treatment of Diphtheria with the Antitoxin.—Dreyfus (*Lyon Médical*, 1895, No. 5, p. 146) relates that from October 15, 1894, to January 21, 1895, 78 cases of diphtheria were treated with the antitoxin at the Charité Hospital of Lyons. Among this number there were 15 deaths, a mortality of 19.29 per cent. Five of the deaths were due to conditions of which the diphtheria was a complication, 1 to typhoid fever, 1 to pneumonia, 1 to diarrhea, and 2 to broncho-pneumonia. In previous years the mortality of diphtheria has been 50 per cent.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM, IN ADVANCE	$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM . . .	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, FEBRUARY 23, 1895.

THE MEDICAL SHARP.

IN commercial life there is a certain rough standard of honesty in buying and selling, beyond which if a man go he is recognized as an unprincipled or a crooked dealer. There are all grades of crookedness, from that of a slight overcharging the trustful and ignorant up to the green-goods business, burglary, railroad-wrecking, and political bossism. In the law, tremendous fees are not seldom charged, but in such cases there has usually been a distinct service performed (by fair or by foul means, it matters not here) of greater value to the client than the price of the lawyer's bill. In the ministry the religious quack hardly gets rich from his "magnetic qualities," and the contributors must be willing to continue the contributions; it is proper enough that they should pay for the pleasure of their deception.

But in medicine, in modern commercial medicine, we mean, there is a rapidly growing condition of things that is like that in no other profession. There is an increasing number of medical men, so-called, who have struck the idea that, irrespective of the value of the service, the more they charge the more they may charge, and the more practice they will get thereby. Other members of the profession are disposed to keep still in the face of these sharpers; but it is high time that the profession arouses itself to the fact that this is a professional matter, and that there is stealing through the community a deep-seated disgust that does not stop with detestation of the individual sharper, but that looks upon medical men as all "tarred with the same stick." The feeling is settling into a sullen grudge and hatred that bodes no good for medicine, because the laboratories, the endowments, etc., which we desire must finally spring from the general feeling of respect in which we are held by the community as a whole.

Take such too common tricks as these: Enticing a patient from the hospital on the ground that in the private office better treatment will be possible, and ending in an exorbitant bill; the outrageous fee to those who will pay it because of fear of scandal, the patient having had specific disease, having had an abortion, etc., etc.; one called in consultation, charging several hundred dollars, and thus exhausting the patient's small stock of money and good will, so that the general physician who advised the consultation can get nothing for his own service; unnecessary or repeated operations with fees geometrically increasing out of all reason; the abuse of the patient's confidence and trust in a special physician, when the thousand-dollar charger knows that many another is quite as capable of good medical or surgical work as himself, and would be glad to do it for one-tenth the money; the flattering of the vulgar superstition that the surgeon is a greater man than the diagnostician and therapeutist, and that the fees for operating should be ten times those for equally arduous and skilled non-surgical work; humoring the hysteric in the insane desire for treatment or for operations; and lastly, the impudent bill of many hundreds or even thousands of dollars simply because it can be collected in whole or in part, and also in order to spread abroad among a few foolish rich the fame of being a "big charger," etc., etc.

There are perhaps a very few asinine *nouveaux riches* who are attracted by such roguishness and who prefer to pay exorbitant fees. If the rogue's practice were limited to such people, there would be less to criticise. But he who plays this flashy game with rich nincompoops will also try it upon the poor and upon those who are not flattered by it, and there then steals through the community a loathing that, as we have said, is not limited to the sinner, but that holds the whole profession accountable. There follows a close bargaining by prospective patients with the most self-respecting physician, in which future fees are stipulated, conditioned, and forced down, and the medical aspect is lost sight of in suspicion and bargaining. After the sharper has "bled" the patient or his friends, the reputable physician must dicker, and is finally made to suffer for the impudent extortion of another. Medical men hardly suspect how widely these stories of the few extortions travel and how long their echoes continue to resound in the community. They neutralize (as few of them as we are glad there are) the thousands of acts of kind charity and self-sacrifice, and leave malevolence and distrust where there should be gratitude and good will.

As a general rule, the fellow who has caught up the trick of huge fees as an advertising and money-making dodge is, of course, a less skilled and less competent physician than another who adheres to principle and honor in his charges. Ten to one he is an arrant quack in all but name. It is only exceptionally that medical ability is coupled with such methods of obtaining money under false pretences. There are always representatives of this class in every city; we all know them well, and we know that their medical and surgical ability is in inverse ratio to their impudence. Alas, that the lay world is not so discerning as we are. And for this reason, as well as for others, the profession owes it to itself to disallow the sharper's attempt to foist himself upon the community as the representative of professional action and custom. We shirk our duty—ay, even our self-interest in the long run, if we "go into our shell" and say, "It is no business of ours," that "people will find him out by and by," and all the other lame reasons for *laissez-faire*. It is of course a puzzling thing to understand whence these sharpers continue to draw their victims; but a large part of the mystery consists in our failure to visit these upstarts with professional condemnation. We assent that they shall wriggle and scheme themselves into professorships, and censorships, and high official medical positions, whereby we publish our own cowardly acquiescence in their supposed professional standing and representative function, and encourage our patients in the delusion which we indeed see through, but which in the end damages our own standing and the good name of medicine itself.

We are heartily in favor of the elevation of medical fees, but we favor an elevation of those of the diagnostician, the obstetrician, the therapeutist, and the refractionist, as well as those of the surgeon, the operative gynecologist, the "cutter," and the cataract-extractor. We favor a general advance in accordance with honor and the general standard of values, and not the brutal and exceptional extortion of the surgical sharp.

REGULATION OF THE PRACTICE OF MEDICINE IN THE DISTRICT OF COLUMBIA.

THERE has been introduced into the Senate of the United States a bill "to regulate the practice of medicine and surgery, to license physicians and surgeons, and to punish persons violating the provisions thereof in the District of Columbia," which has been read twice and referred to the Committee on the District. The bill also provides for the regulation of the practice of midwifery by women not physicians. The bill provides for the creation of a board of medical supervisors composed of the presidents of three boards of medical examiners (regular, homeopathic, and eclectic), of five members each, and two members to be appointed by the Commissioners of the District, and in most respects conforms to similar laws already in force. The position of THE NEWS on the question of legislation for the regulation of medical practice is so well known as not to demand repetition. The bill before us, however, contains certain objectionable features, the failure to remove which must in a large measure defeat the very objects of its enactment. Thus it is stipulated that

> "Any applicant intending to practise in the District of Columbia any system of medicine or treatment other than the regular or homeopathic or eclectic system, and stating such intention in his application, shall be exempt from such part of any examinations to which he may be subjected as relates exclusively to the treatment of disease, but such applicant shall submit in all other branches to the same examinations as are required of other applicants, and shall be examined by such board of examiners as may be designated by the board of medical supervisors; *Provided*, That any person who may avail himself of the exemption allowed by this clause, and who receives a license under this act, shall cause at all times to be plainly affixed to any sign or signs he may erect or cause to be erected, and to any prescription-blanks, bill-heads, and other like articles he may use in his professional work, and to be inserted in any advertisement he may cause to be displayed, the designation of the system of medicine or treatment employed by him for the cure or relief of disease."

This is objectionable as tending to invite and encourage quackery of all sorts and stamping it with the seal of legitimacy. It further recognizes and sanctions methods of seeking notoriety that are contrary to the spirit of the best professional ethics. On the contrary, it were desirable to have some provision made looking to the prohibition of public advertisement of ability to treat and cure certain diseases, such as forms a part of most legislation for regulating the practice of medicine. Finally, it would be well for the bill to be so amended that of the two members of the board of medical supervisors appointed by the Commissioners of the District both shall not be adherents of any of the three so-called systems of medicine named in the bill, in order that none should acquire a majority in the board.

Rational regulation of the practice of medicine has in view the protection of the public, and can only inure to the benefit of the community. All good men will unite in the effort to suppress quackery and charlatanry. As the central seat of government, and in a sense the representative city of the United States, Washington and the District of Columbia should have been the first to enact legislation regulating the practice of medicine within its bounds, and protecting the health and lives of its citizens; but "better late than never"—in doing good.

EDITORIAL COMMENTS.

"Uranalysis."—We have been taken to task by the learned author of *Purdy's Practical Uranalysis* and by the *New York Medical Journal*, for criticising (in our review, p. 26, January 5, 1895) the term *uranalysis*. Both critics courteously blame us, and aver that *uranalysis* is the proper formation of the word, and that *urinalysis* is, so to speak, a barbarism. But we are sorry to find no reasons, or no valid ones, adduced for this opinion; and we are still more sorry, at least tentatively, and always humbly, to differ from such competent authorities. In our opinion, all the objections that can be adduced against *urinalysis* are doubled in number and trebled in force against *uranalysis*.

1. In the first place, *urinalysis* has had and still has the field. However objectionable etymologically a term may be, possession, in philology, is even more than nine points of the law. Any attempt to supplant a word in use is almost always in vain, and is like resisting the tide. One can never reach the sources of the perversion, because they are behind us and beyond us. But if one hazard the impossible task, he must have patently sound and evident reasons.

2. We suppose the chief objection to *urinalysis* to be against the elision of the syllable *an* of the second part of the compound, *analysis* (Greek, *ἀνάλυσις*). But in *uranalysis* there is an elision just as culpable, or more so, of one syllable of the other root, *urin-* (Latin, *urina*). Why is the elision blameworthy in the one case and praiseworthy in the other?

3. The whole question of both formations revolves about an absurdity. The dictionaries derive the compounds of *ur-* and of *urin-* from the Greek *οὖρον*—an evident blunder, as they are patently derived from the Latin, and these hybrids, such as *uremia*, etc., are simply hybrids, none the worse for the fact, except for the silly attempt to conceal their parentage by false etymologies, this now-you-see-it and now-you-don't derivation. The stickling for pure and logical formation as applied to our medical barbarisms is nowhere more laughably illustrated than in the whole series of words pertaining to the urine.

Wherefore the prejudice against the hybrid? To us it seems the argument of the purist and the puerile. As our modern coinages did not grow out of the Greek or Latin, but are simply new creations using the old roots as excuses, why should not the two parts of a compound medical word be derived from two languages? What earthly objection is there to it? Was language made for man, or man for the sake of language? Whoever shall attempt to banish hybrid words from medical language will have undertaken a task at once impossible and absurd. We confess, indeed, to a great respect for mules; they are not so showy as horses perhaps, but they are quite as beautiful as asses, and far more useful and economic, all things considered, than either horses or asses.

4. A weighty objection to *uranalysis*, as a newly introduced word, consists in the fact that it is identical with, and, therefore, liable to be mistaken as a designation of facts like those now expressed by any of the other *urans*. *Uran-* is now already used to signify about a dozen things, one of the nine muses, one of the minor planets, a genus of plants, a mineral, one of the elements, one of the major planets, a mythologic deity, a dye-stuff, the palate, a form of megalomania, etc., etc. It would seem inadvisable to load these two syllables with further diversity of significance, whilst the root *urin-* has but a single meaning.[1] Philologically we do not assent to the doctrine: For whosoever hath, to him shall be given, and he shall have more abundance; but whosoever hath not from him shall be taken away even that he hath.

If one's philologic conscience is so hypersensitive as to object to *urinalysis*, it would seem that it must surely balk at *uranalysis*. In this event we would advise a trial of *ouronanalysis*, which is *not* a hybrid, and which is perfectly correctly formed. *Urinanalysis* is also correct, and is one letter shorter than *urine-analysis*. But why cherish fondly either or any of the objectionables? *Urine analysis* or *analysis of the urine* seems pretty good English.

---

[1] This objection has also struck others. Since the foregoing was written the *Liverpool Medico-Chirurgical Journal*, January, 1895, p. 206, has said:

"Life is not so very short, or the use of the words 'urinary analysis' so very frequent, that it would severely tax any writer's time to employ the clearer double word than the obscure and doubtful single one which forms part of the title of the book under consideration. The meaning of 'urine analysis' is plain and unmistakable; not that of 'uranalysis,' seeing that it may apply to many things, such, for example, as 'urea analysis,' 'uranium analysis,' 'uranite analysis,' 'uryle analysis,' etc."

The Dynamics of Life is the title of a most interesting lecture—interesting to those whose thought runs naturally to the deeper problems of physiology and neurology—by that great neurologist, Dr. W. R. Gowers. The address was delivered October 3, 1894, before the Medical Society of Manchester, England, and was published in the *Lancet*, and has, we believe, been republished as a pamphlet in our country. There is in it a remarkable lucidity of thought upon a somewhat recondite subject, and a delightful simplicity of language, almost convincing the reader that in reading he knows considerably more about the matter than in sober reality is demonstrably known. The spirit of a brave and scientific use of the imagination is altogether praiseworthy. Dr. Gowers finally admits that the title he uses is a misnomer, that he does not attempt to deal with the dynamics of life, properly speaking, but only with some of the fundamental processes of physiologic and nervous function. By the aid of careful inference and a sort of philosophic diagnosis by exclusion we are led step by step onward into the mysteries of physiologic physics, until we reach the inscrutable mystery lying behind all biologic function—the mystery of vitality, or of Life. On one page we are somewhat lonesomely left in a kind of agnostic heaven concerning "vital energy," but upon the next page we are reassured that "there is more in Life than the processes it controls." The inference remains—and we are surprised that our lecturer does not draw it—that the fact of the "control" by Life of these "processes" is absolutely indisputable. But the directional control of physical forces demands, by inescapable logic, an added increment of "energy" in the realm of measurable, or physical, phenomena. No one is more ready to follow the leading and logic of facts than Dr. Gowers: why then balk at the conclusion that the perception and weighing of this added energy of control only await the finer perceiver and the more delicate scales to make it just as apparent to science as that of an experiment with the bolometer or the torsion-balance. Lord Kelvin has said that we know more of the ether than we do of shoemakers' wax. There are some minds that fondly think themselves "scientific" that have so little confidence in logic or the laws of mind that they doubt if two apples and two apples make four apples, unless the apples be there before them with which to prove the suspicious proposition, and even with the necessary articles before them they would hardly admit that two apples and two spoons make four things. The mind of Dr. Gowers is by no means of this order, and he knows that inference and logic and imagination always precede scientific demonstration. Such a logical faith as we have indicated seems fully as necessary and imperative as many statements agreed to in the essay. With this one added step frankly taken the mournfulness of the splendid comparison of the mystery of disease and the problem of Life to the sphinx "that looks but cannot see," is transformed into the assurance of spiritualized insight that sees without the need to look.

The Saving of Life from Drowning and the Resuscitation of the Apparently Dead.—Old lines of usefulness are constantly widening and new ones forever opening. While, perhaps, the dangers to life have increased, the means of protection and prevention have kept pace. Some lives are lost through ignorance, some through carelessness. That many lives are lost that could be saved by the observance of simple precautions or the application of simple measures in trained and intelligent hands requires no elaborate discussion. The Life-Saving Society is the name of a London institution, organized in 1891, for the purposes of promoting technical education in life-saving and in resuscitation of the apparently drowned; of stimulating public opinion in favor of the general adoption of swimming and life-saving as a branch of instruction in schools, colleges, etc.; of encouraging floating, diving, plunging, and such other swimming-arts as would be of assistance to a person endeavoring to save life; and of arranging and promoting public lectures, demonstrations, and competitions, and to form classes of instruction, so as to bring about a widespread and thorough knowledge of the principles that underlie the art of natation. The society has been highly successful in its efforts, and has issued a *Hand-book of Instructions for the Rescue of the Drowning*, which has reached its third edition and its seventeenth thousand. This well-printed and illustrated booklet of 107 pages contains much useful information which, if properly availed of, must result in great saving of life, as well as affording a delightful and healthful means of exercise. The course of instruction is both theoretic and practical, and is carried out on land and in the water by means of drills described in the *Hand-book* Certificates of proficiency and bronze medallions are awarded to those that give satisfactory evidence of efficiency to render aid to persons in danger of drowning, nearly four hundred having been awarded during the past season. The work is done without remuneration, and is supported by voluntary contributions. H. R. H. the Duke of York, K. G., is the honorary president of the society; W. H. Greenfell, Esq., the acting president; Mr. Edmund V. Salaman, the honorary treasurer; and Messrs. Arch. Sinclair and Wm. Henry, the honorary secretaries; and the officers of the society are at 3 Clarendon Square, London. We do not know that branches of this worthy organization or that any similar organization exists in the United States, but the formation of the one or the other would be a most praiseworthy undertaking that could only be productive of a vast amount of good.

Personal Hygiene.—There are certain subjects that may be designated "border-line" that fail to receive the consideration that they deserve from either the popular or the educational or the scientific writer. For the one they are somewhat too prosaic, for the others perhaps too trivial. A book or a series of books on the subject of personal hygiene would, we are sure, fulfil a most useful purpose. Sundry scattering efforts have been made in this direction (notably Dr. Burt G. Wilder's capital little booklet, *Health Notes for Students*, published by Putnam's Sons), but scarcely any worthy the importance of the matter. It is true we have works on the care of the mouth and of the teeth, of the throat and of the voice, and of various other individual parts of the economy, but so far as we know there does not exist a systematic dissertation upon the hygienic care of the whole body, including the management of the skin, the hair, the nails, the eyes, ears, nose, the genito-urinary organs, and the anus. There is both an art and a science in personal hygiene, but they have not received the development that their importance entitles them to. We are moved to these remarks by a timely article in the *Journal of the American Medical Association*, January 12, 1895, p. 46, by Dr. J. Rawson Pennington, on the "Hygiene of the Anus and Contiguous Parts." The subject is rather a homely one, but receives considerate treatment. There can be no doubt that many of the rectal and anal troubles which are so prevalent can be ascribed to neglect in the care of these parts. Constipation, straining at stool, the injudicious use of purgatives, the position necessitated by the modern water-closet, the failure of simple ablution, the use of unsuitable toilet-papers or worse are among some of the influences that may be held responsible for such conditions as hemorrhoids, fissures, ulcers, prolapse, inflammatory processes, reflex phenomena, and mechanical distubances of adjacent viscera. In this era of preventive medicine the dissemination of a proper knowledge of the physiology of the outer textures and accessible organs of the body is essential, and will go far to limit a numerous class of avoidable ailments.

Strange Logic is that of our usually consistent and always excellent contemporary, the *Boston Medical and Surgical Journal*, when it would charge President Eliot with the responsibility of broken bones in the future from foot-ball playing. President Eliot frankly condemns the game in words we quoted in our issue of February 9th. In trying thus to stop the vicious excesses of the game he is to be made responsible for injuries resulting from those excesses! Partisan logic could surely go no further. To-day Captain Bahen, of Washington, lies slowly dying, paralyzed from the chest down, from fracture of the spine, occurring months ago on the foot-ball field. We suppose that this "trivial accident" and the hundred or more of deaths that have occurred on the foot-ball field are to be charged to the "extremists" who have opposed this atavistic reversion to barbaric "sports." Such logic and such reckless indifference to human suffering are doing excellent service in awakening parents and educators to the pernicious influence of the "game."

SOCIETY PROCEEDINGS.

NEW YORK NEUROLGGICAL SOCIETY.

Stated Meeting, February 5, 1895.

Dr. C. A. Herter, Vice-President, in the Chair.

"Charcot Monument Fund." Dr. Herter, Chairman of the Charcot Monument Fund Committee, reported that $533 have been received. This amount was mostly made up of large subscriptions, and there has been a lack of general interest in the matter. The committee hoped to increase the amount to $800, or $1000, so as to make a really worthy contribution to the general fund, and in order to accomplish this it was very desirable that each member of the society should contribute something, no matter how small the amount.

"Athetosis with Beginning Tabes." Dr. Joseph Collins presented a male patient, thirty-seven years old, married, and by occupation a policeman. The family history was very good. Syphilis and alcoholism were denied, and there were no traces of either to be found. The man had never used tobacco nor indulged in excesses. The only factor in his previous history that was at all pertinent was that nearly eight years before coming under observation, while attempting to make an arrest, he was thrown against a pillar of an elevated railway, and received a severe cut over the right parietal region. He was not unconscious, but was incapacitated for about three weeks. There had at no time been any headache.

For a year there had been noticed some involuntary movements of the right hand, particularly on excitement and exertion. Accompanying this was a sense of numbness in the hand and upper right extremity, and a loss of dexterity in the fingers of this hand. There was also drooping of the left eyelid, at first intermittent, but subsequently constant. Further, transient attacks of diplopia occurred. The numbness of the right hand and arm gradually grew worse, and the member felt heavy and useless. For a short time a similar feeling of numbness had been perceived in the legs, particularly in the left, together with the sensation of a firm band fastened around the calf of the right leg. Sexual vigor had begun to diminish within six or seven months, until gradually a state of impotency was reached. There was no trouble with the sphincters, and there had been no disturbance of speech and no uncertainty of gait, either by day or by night.

Examination showed more or less irregular movements of the right upper extremity, particularly manifest in the hand. These movements constituted neither a clonus nor a tremor, nor were they sufficiently rhythmic, determinate, systematic, or uniform to be called athetoid, and there was no tendency to distortion. They continued during sleep, but to a less degree, and were aggravated by stimulation and excitement. They consisted in a sort of flexion and extension of the hand on the wrist and irregular movements of the fingers. They could not be diminished by the strongest endeavor on the part of the patient. The strength of the right arm was a little impaired, more in the extensors than in the flexors. There was considerable tactile anesthesia, but the pain-sense and thermal sense were normal. The muscular sense was impaired, and there was loss of the sense of position in the right arm. When a coin, such as a silver quarter-dollar or half-dollar, was dropped into the palm, the man could feel it strike, but he had no idea what it was, nor could he tell when it was removed. There was marked ataxia in this extremity, complete loss of dexterity in the fingers, and great over-action on attempts at directed effort. The left palpebral fissure was narrowed, but there was no real ptosis; the left eye seemed small and retracted, while the pupil was pin-head in size and did not react to light and very slightly in accommodation; there was no muscular deficiency. The pupil of the right eye was small; it reacted in accommodation, but not to light. There was no limitation in movement or of the visual field in either eye.

Both optic nerves were pale, the left rather more so than the right. It was thought they were possibly in the first stage of atrophy. Vision, R. 20/L; L. 20/XL; color-perception was good; there was no scotoma.

The knee-jerks were completely absent, even with reinforcement. Station was steady. There was no twitching of the left hand, but the fingers had lost their dexterity to some extent. There was slight numbness in the left upper extremity, but objectively sensibility was normal. There was no muscular atrophy. Although the patient strenuously denied syphilitic infection, and there was no evidence of the disease, he was put upon mercurial inunctions and increasing doses of potassium iodid. This treatment, combined with warm baths, rest in bed, massage and tonics, was kept up for ten weeks, and at the end of that time the patient had not shown the slightest sign of improvement, excepting the return of sexual potency. The treatment was then changed to gold and arsenic chlorid.

Dr. Collins regarded the case as one of athetosis, with beginning tabes. This combination is rather rare, only a few cases having been reported. The only symptoms of tabes in this case were the loss of knee-jerks and the condition of the man's eyes. He had never had any pains.

Dr. M. Allen Starr said the case impressed him as one of multiple lesions, and in the absence of pains, together with the marked unilateral character of the symptoms, it differed very decidedly from locomotor ataxia. A person may have ataxia without necessarily having locomotor ataxia, and it may be the result, as may also the loss of knee-jerks, of a lesion in the pons, or crus, or cerebellum.

Dr. B. Sachs said that on account of the multiplicity of the man's symptoms he did not regard the case as one of locomotor ataxia, pure and simple. He rather suspected that the case was one of cerebro-spinal syphilis. He expressed the opinion that one of the most certain symptoms in cases of syphilitic tabes—as distinguished from pure tabes—is an inequality in the pupils; either they are unlike, or they do not act alike.

Dr. Starr said that he felt inclined to agree with a statement made by Dr. Buzzard, of London, in a recent book, that multiple sclerosis is a much more frequent disease than has heretofore been supposed. That writer reports five cases of multiple sclerosis in which the ordinary diagnosis would be locomotor ataxia.

Dr. Collins said that he regarded the case as one of cerebro-spinal syphilis of the tabic type. The patient was seen a number of times by Dr. C. L. Dana, who made the same diagnosis. Dr. Collins added that he did not think it possible to have a lesion of the crus or cerebellum without the development of certain motor and other symptoms which this man did not present. This man probably had syphilis many years ago, and there was now some thickening in the capsule that gives rise to the athetosis.

Dr. Herter said that he thought the case was one of multiple sclerosis rather than cerebro-spinal syphilis. He did not consider it one of locomotor ataxia. It is perfectly possible to have a lesion of the crus that gives rise to anesthesia and incoördination on one side. In many cases of multiple sclerosis one of the early symptoms is slight optic atrophy.

"A Contribution to the Subject of Tumors of the Spinal Cord, with Remarks upon their Diagnosis and their Surgical Treatment, with a Report of Six Cases, in Three of which the Tumor was Removed." Dr. M. Allen Starr stated that the diagnosis of tumors of the spinal cord has only become possible with any degree of accuracy within the past few years, since the localization of the motor and sensory functions of the cord has been precisely determined. The practical importance of a subject of this character cannot be exaggerated, inasmuch as a study of the cases upon record shows that relief of the symptoms and cure of the disease are perfectly possible by surgical interference in the majority of cases when the diagnosis is made in time.

From a careful review of the literature of the past ten years he had been able to collect 123 cases of tumor of the spinal cord. In 100 of these the history was fairly satisfactory, and in the light of our present knowledge a diagnosis should have been quite clear some time before death. In 54 of the cases it should have been possible to reach not only a diagnosis, but also a conclusion as to the feasibility of an operation. Studying the cases from a pathologic standpoint, it was found that of the 100 cases there were 75 in which the tumor could have been removed. As a matter of fact, operations had been undertaken for the relief of tumor of the spinal cord in 22 cases (not included in the 123 cases previously referred to). In only two instances had the surgeon failed to find the tumor sought for; in but one was it impossible to remove it when found. In 11 cases the patients died soon after the operation; in 11 cases they recovered from the operation. In 6 cases the operation was followed by recovery from the condition of paraplegia. After fully reporting 6 cases of tumor, in 3 of which the diagnosis was made and the tumor successfully removed, Dr. Starr said that the most important and earliest symptom of tumor of the spinal cord is pain. The location of this pain is usually in the peripheral distribution of the nerve-root that is first compressed by the growth of the tumor. In the majority of cases the pain is referred to the epigastrium or to the abdominal region, or to the legs or arms, rather than to the spine itself. The pain is of a severe neuralgic character, is sometimes described as burning, and as it increases, it appears to shoot along the course of the nerve that is implicated. The second group of symptoms of diagnostic importance are those caused by the compression of the cord by the tumor. It is well known that when compression is exerted either upon a nerve-trunk or upon the spinal cord, a certain order is commonly observed in the symptoms produced, viz.: (1) pain referred to the periphery; (2) increase of reflex activity; (3) paralysis; (4) loss of sensibility; (5) loss of reflex activity. In the vast majority of cases tumors of the cord have been found in the dorsal region.

A summary of the cases collected from the literature of the past ten years showed that thus far the number of recoveries after the removal of spinal tumors has been but six, and in one of these the compression was exerted upon the cauda equina and not upon the cord proper. It must be said in explanation of these unfavorable results that the operation was not undertaken until the tumor had been present for a number of months, and until the secondary destruction of the spinal tissue was of such a nature that regeneration of the nerve-elements was practically out of the question.

In spite, however, of the gravity of the situation, and of the very unfavorable results that have thus far attended the removal of spinal tumors, it is always to be remembered that the disease is otherwise of a hopeless character and of a necessarily fatal termination, and, hence, any measures for its relief are justifiable. It is also to be remembered that the earlier the diagnosis can be undertaken, the more likely it is to be followed by relief.

Attention was called to the relation of the segments of the spinal cord to the vertebræ, and it was pointed out that tumors lie from two to four inches above the line of anesthesia on the body. Large incisions, the removal of the bone by cutting forceps and rongeur, the cautious division of the dura and care in handling the cord to prevent hemorrhage and pressure were recommended.

Dr. C. L. Dana said that cases of spinal tumor have been rare in his experience. He recently saw a case in which he felt inclined to make that diagnosis, although he could not say positively whether the lesion was a tumor or not. The patient was a female, aged thirty years, who was operated on about a year ago for carcinoma of the foot, the leg being removed above the knee. The patient made a good recovery and remained well until about nine months after the operation, when she began to suffer from neuralgia on the right side, in the region supplied by the seventh and eighth dorsal nerves. She gradually grew weaker, and there was a certain amount of cachexia. Four months after the onset of the pain paraplegia developed which, within a week, became complete for both motion and sensation. There was a loss of control over the sphincters, and the woman presented all the symptoms one would expect from a transverse lesion of the cord. The sudden onset of the paraplegia made it probable that in this case there was a malignant growth of the cord, with, perhaps, acute softening due to hemorrhage or embolism. Dr. Dana added that thus far the result of the surgical treatment of tumors of the cord is rather discouraging; perhaps it will be better in the future, when the tumors are recognized earlier.

Dr. Sachs said that this subject evidently possesses a greater interest now than it did a number of years ago when Erb made the statement that spinal tumors were of so little importance that he did not care to enter into their differential diagnosis. It is doubtful, however, whether the practical importance of the subject will, in years to come, prove to be much greater than it has been in the past. In most of the cases reported as operated on with good results the tumor was extra-dural. In the diagnosis of these cases it is a point of the greatest importance to try to make out whether the growth is extra-dural or intra-dural. Further, it is important to differentiate between the extra-spinal and intra-spinal. When the cord itself is involved, it is very doubtful whether anything can be gained by an operation.

Dr. Sachs said that while he was perfectly willing to acknowledge the value of pain as a means of diagnosis in these cases, he thought Dr. Starr had laid rather too much stress upon this. The pain is produced by tumors that rest chiefly on the posterior surface of the cord, and while undoubtedly a large number do take their origin in that region, perhaps the majority, still there are some, particularly those in connection with caries, that would be likely to give rise to symptoms referable to the anterior nerve-roots rather than to pain. These so-called root-symptoms are often very important. Before advising an operation in these cases, it is well to try to arrive at a conclusion as to the character of the growth. In cases in which there is any suspicion of tuberculosis, it is doubtful whether one should operate; also in specific cases. The operation is of so serious a nature that everything must be carefully considered before it is resorted to. Dr. Sachs called attention to the fact that some cases in which the symptoms might very well lead one to suspect tumor might prove to be cases of localized specific meningitis. Such instances have come under his observation. Thus far, the results following spinal operations have been extremely discouraging, and the prospects are even more gloomy than with brain-tumors, or fully as much so. After the removal of spinal tumors, the patients, for some reason which has not been determined, do not seem to improve. This is probably due to structural changes in the cord, so slight in extent that they are not noticeable to the naked eye.

Dr. A. J. McCosh discussed the subject from a surgical standpoint. He stated that at the present time the outlook in this field of surgery is rather gloomy. One obstacle to the attainment of brilliant results lies in the character of the growths. The great majority of spinal tumors seem to be either malignant or tuberculous, and in either case very little can be expected from their removal. The operation of laminectomy, *per se*, is not a formidable one; it is rather tedious, and considerable blood is likely to be lost; but if the patient is in fair condition the mortality should not be great. His own results with the operation have not been encouraging. He has operated four times, and in none of these cases did any benefit follow the operation. Still, it must be remembered that these are otherwise hopeful cases, and if an operation offers a reasonable hope for relief it should be undertaken.

Dr. Herman M. Biggs said that in the cases of malignant tumor of the cord that he has seen at autopsy there were invariably similar growths in other parts of the body and secondary tumors in the brain. The only kind of tumor of the cord in which the prognosis is at all favorable is the non-malignant connective-tissue neoplasm, such as has been removed by Dr. McEwen. In cases in which the growth is tuberculous or malignant the course of the disease is probably much more rapid than when it is non-malignant, and this fact might give some clue as to the character of the tumor and the advisability of operative interference.

Dr. Herter said that he had seen a number of cases of tumor of the spinal cord, and has recently reviewed the literature of the subject. In doing this he was impressed with the idea that the time had not yet arrived for writing the history of spinal tumors. A sufficient number of these cases have not yet been accurately reported. Dr. Starr has done great service in calling attention to the sensory disturbances met with in these cases and by his careful study of them. He fully agreed with Dr. Starr that pain is the most constant and characteristic as well as the earliest symptom of tumor of the cord; it is much more constant than in brain-tumor.

As regards the character of these growths, Dr. Herter said that of the cases thus far reported carcinomata do not form a very large proportion. The sarcomatous and tuberculous are more frequent, and many of them begin in the spinal cord itself. The gray matter of the cord seems to afford a favorable nidus for the growth of tubercle-bacilli. Probably one-half of the tumors of the cord will never be classed as operable.

Dr. Starr, in closing the discussion, said that he had thus far been unable to find any definite points of differential diagnosis between extra-dural and intra-dural tumors of the cord. There are some points of differentiation between the intra-spinal and the extra-spinal, including under the former heading both the intra-dural and extra-dural. With the intra-spinal there is more likely to be an early development of bedsores and cystitis; also reaction of degeneration and atrophy of the muscles. The supposed rarity of these cases is probably largely due to the fact that they are often unrecognized. The same is true of other diseases. Eight years ago syringomyelia was rarely met with; since that time the disease has been studied and well described, and last year sixty-eight cases were reported. Dr. Starr said that within a year his paper on spinal tumors will no doubt be outgrown, but he expressed the hope that it would lead to a more careful study of these cases. The statistics thus far are not so discouraging, and there is every reason to hope that they will be better in the future. Of twenty-two cases thus far operated on, six recovered from the operation and the paraplegia—that is, more than 25 per cent. It is true that in most cases the character of the tumor is such that recurrence is to be feared; still, surgeons do not hesitate to remove a sarcoma in other parts of the body, even though the probability is that it will recur.

NEWS ITEMS.

Diphtheria-Antitoxin in Cleveland.—Dr. A. P. Ohlmacher, professor of pathology and bacteriology in the medical department of the University of Wooster, assisted by Drs. C. B. Parker and H. W. Kitchen, has completed the immunization of a horse against diphtheria. The first injection of 0.5 c.c. of the toxins was made on December 20, 1894, and the last injection of 250 c.c. was made February 5, 1895, thus completing this part of the experiment in the incredibly short space of one month and sixteen days. The toxins manufactured and employed in this work were of high virulence, 0.1 c.c., invariably killing a 500-gram guinea-pig in from thirty to thirty-six hours; and their potency has been repeatedly tested during the work. The first blood-serum was obtained on February 9th, and in the preliminary tests on three guinea-pigs showed strong immunizing power, as all three of the experiment animals were still alive and well three days afterward. It now remains to standardize the antitoxin and it will be ready for therapeutic purposes. The animal treated, it is believed, is the first completely immune horse in this country, and, from all that can be learned, it has been immunized in a much shorter period of time than any before. Roux completed the immunization in two months and twenty days, and cited the fact as remarkable.

The work in the laboratory of the University of Wooster has been done for purely scientific purposes, and the antitoxin will be used only in cases in which preliminary bacteriologic examinations can be made. The antitoxin will not be put in commerce. A detailed report was made before the Cleveland Medical Society on February 22d, together with an exhibition of all possible material bearing on it. The report will be duly published.

To Military and Naval Medical Officers.—Dr. Albert L. Gihon, Medical Director U. S. Navy, U. S. Naval Hospital, Washington, D. C.; Dr. John VanR. Hoff, Major and Surgeon U. S. Army, Governor's Island, Harbor of New York, and Dr. Myles Standish, Captain and Assistant Surgeon, M. V. M., No. 200 Dartmouth Street, Boston, Mass., members of the "Committee on Litter," appointed by the Association of Military Surgeons of the United States, to report at the approaching annual session a desirable form of military litter for the comfortable, safe, and expeditious transportation of the sick and wounded, solicit from medical officers of the National Services and the National Guard of the several States suggestions, plans, or models of such an appliance, to be delivered to either of them at their respective addresses on or before April 1, 1895.

A Journal for Diseases of the Digestive Organs.—The department of "Diseases of the Digestive Organs" is about to be represented by a publication, the *Archiv für Verdauungskrankheiten*, the first number of which will appear in April. It will be published in Berlin and edited by Dr. I. Boas, the well-known author of a work on *Diseases of the Stomach*. He will be assisted by specialists in Germany and other countries. The *Archiv* will contain original articles, besides reviews and abstracts of recent literature, and will embrace diseases of the stomach, intestines, liver, pancreas, and peritoneum, constitutional diseases and dietetics.

The Section on Neurology and Medical Jurisprudence of the American Medical Association has arranged the following symposiums for the May meeting at Baltimore:

Epilepsy: Medically, Surgically, and Therapeutically. Hypnotism and Mental Therapeutics, and its Medico-Legal Relations. Electricity: Some new Therapeutic Relations and Questions of Treatment.

Short practical papers on these topics are urgently solicited. Other papers on subjects belonging to this section will be welcomed. Dr. T. D. Crothers, of Hartford, Conn., is the secretary of the Section.

The Obstetrical Society of Cincinnati at its annual meeting elected the following officers for the ensuing year: President, Dr. A. W. Johnstone; Vice-President, Dr. Sigmar Stark; Secretary, Dr. E. S. McKee; Corresponding Secretary, Dr. W. D. Porter; Treasurer, Dr. Geo. E. Jones.

Prof. Jacob Gottstein, of Breslau, the well-known laryngologist, died January 11th at the age of sixty-three.

THE BLOOD-ALTERATIONS OF ETHER-ANESTHESIA.[1]

BY JOHN CHALMERS DA COSTA, M.D.,
DEMONSTRATOR OF SURGERY IN THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

UNCONSCIOUSNESS is the dethronement of the reigning forces of the nervous system and the destruction of all central authority, the reduction of cerebral activity to basic and fundamental elements, and the annihilation of the higher psychomotor activities. In other words, unconsciousness is the state of automatic and uncontrolled activity of individual nerve-elements. Artificially induced unconsciousness is known as anesthesia. The anesthetic state may be produced by a sudden diminution of the amount of blood in the brain, as is seen after severe hemorrhages. The knowledge of this fact was utilized in the French hospitals before the days of ether and chloroform, the surgeons producing anemia of the brain by suddenly lifting a man into an erect position from a recumbent posture; the state of anesthesia thus induced permitting the performance of slight operations. Diminution of the blood-supply of the brain by ligation of the carotid artery may produce the same effect. Furthermore, it has long been recognized that partial anesthesia follows forcible and rapid respiration, probably as a result of anemia of the brain.

Anesthesia may be produced by alteration in the composition of blood and the carrying in this fluid of certain extraneous materials to the nerve-centers. This form of anesthesia is exhibited in the carbonic-acid narcosis, in which condition, the internal respiration is diminished and the activity of the cerebral cells is depressed or destroyed. Another example of anesthesia by alteration in the composition of the blood is seen in the inhalation of ether or chloroform.

For almost fifty years ether has been under scientific investigation, and it is generally agreed that it acts on the nervous system as does alcohol, only far more rapidly. When given by inhalation there are four stages of anesthesia:

1. The stage of stimulation, characterized by excitment and a pleasing intoxication.
2. The anodyne stage, characterized by impaired sensation, retained reflexes, delirium, which is most marked in robust individuals, tetanic contraction of the muscles, turgescence of the face, etc.
3. The anesthetic stage, characterized by the abolition of the ordinary reflexes and of all conscious excito-motor sensibility.
4. The paralytic stage, characterized by diminution of unconscious excito-motor sensibilities, and, finally, by death from paralysis of the respiratory center.

The condition of anesthesia is thought by most observers to be due to the passage of ether into the blood and the subsequent direct action of this drug upon the nerve-elements. Prevost has sought to prove this by a well-known experiment. He produced unconsciousness in a frog by the direct application of the drug to the cerebrum after first tying the aorta to prevent the washing away of the agent by the force of the circulation. The defect in his experiment is the fact that the ligation of the aorta alone, by depriving the brain of blood, might be responsible for the unconsciousness.

It seems highly probable, from a series of observations I am about to submit, that the cause of the anesthetic state is not merely the direct action of ether upon the nerve-elements, but involves likewise an alteration in the composition of the blood. It is a well-known fact that slow, chronic, advancing nutritive failure of the brain is first manifest in the decay of the higher and most unstable faculties, which are the last products of evolutionary advance, and that the last faculties to suffer are those that are purely automatic. Consciousness is not lost early in these conditions, because cells producing cerebral activities, of which consciousness manifests the sum, have time in chronic failures to adjust themselves to their altering environment.

We notice this course of events in general paralysis of the insane; the higher faculties of memory, of will, of judgment, of abstraction, and of attention are lost first. Attacks of loss of consciousness due to sudden and limited nutritive failures from congestions or capillary hemorrhages come upon the scene; the emotions are altered, perverted and uncontrolled, and finally, if life be sufficiently prolonged, all faculties but the purely automatic are destroyed and the individual passes into a condition exactly comparable to the coma of alcoholic intoxication or to the anesthetic state induced by ether.

Any condition that suddenly alters the composition of the blood must prevent nutrition, retard the removal of waste products, and fix the molecules of nerve-matter, and may thus produce temporarily a condition analogous to the persistent state of mental deterioration. Diminution in the amount of blood in the brain is known to produce this condition. Altered composition is known to have a like effect, as when the blood holds carbon dioxid in large amounts; and yet in ether-anesthesia, neither diminished quantity of blood in the brain nor the presence of carbon dioxid in the blood serves to explain all of the observed phenomena. It seems evident that altered nutrition and a failure to remove waste products might depend upon the absence of proper oxygenation as well as upon the presence of carbon dioxid. Diminished capacity for oxygenation means diminished amount of oxygen in the blood; and lessened amount of oxygen means a lessened amount of the oxygen-bearing element, that is, of hemoglobin. Diminished amount of hemoglobin suddenly brought about would theoretically cause malnutrition and unconsciousness, and if this condition is found to maintain in the anesthetic state we can account for the prolonged depression induced in some by the inhalation of ether, and for other conditions that have previously lacked comprehensive explanation.

---

[1] A contribution from the Kyle-Da Costa Laboratory, Philadelphia.

That the diminution of the amount of oxyhemoglobin does tend to produce unconsciousness is shown by the drowsiness, the heaviness, and the tendency to syncope shown by sufferers from chlorosis, by the almost comatose condition of the victims of Winckel's disease, and by the abolition of sensibility of rabbits and guinea-pigs in which this disease has been artificially produced, and yet in these conditions the alteration of blood-composition is rather gradual than sudden.

The following observation will show that diminution in hemoglobin is constant after the inhalation of ether; that the diminution is rapid and marked, is accompanied by alteration in the shape of the corpuscles, but by no marked diminution in their number. This diminution in the amount of hemoglobin is so pronounced in the anemic as to give conclusive evidence of the reason why reaction in these cases is often so difficult and the effect of the anesthetic so persistent and prolonged.

The exact mode in which the hemoglobin is removed from the corpuscles is questionable. Practically we know that if blood outside of the body is subjected to a low temperature, and subsequently warmed, the coloring-matter of the corpuscles passes into the blood-liquor. Theoretically we may assume that the rapid evaporation of ether in the air-cells of the lungs produces great cold, and that the blood circulating through the rest of the body becomes subsequently warmed, and the hemoglobin is thus removed.

This theory finds apparent confirmation in the rapid lowering of temperature induced by anesthetics, a lowering that begins with the anodyne stage, and that may reach the extent of four or five degrees. In the cases in which I have made studies of temperature the average fall was found to be from one to three degrees, a fall separated from the fall of shock by the fact of the rapid ascent of the temperature on cessation of inhalation of the anesthetic.

The altered shape of the corpuscles may in part be due to the removal of the hemoglobin, and in part to the dissolving out of some of the fat which they contain. What becomes of the hemoglobin removed from the corpuscles is a question, though the occasional occurrence immediately after etherization of severe jaundice would seem to indicate that in some cases at least this pigment goes to the liver, and is there broken up. In confirmation of the foregoing views I submit twenty-nine cases in which blood-examinations have been most carefully made before, during, and after etherization.[1]

The counts were made by means of a Thoma-Zeiss hemocytometer; the hemoglobin was estimated by means of Gowers' and Fleischl's hemoglobinometers; drawings have been made from the undiluted blood, and of necessity are diagrammatic; all forms of the red corpuscles being represented by red; leukocytes, by pale-blue; lymphocytes, by dark-blue; and blood-plates by green.[2] In making the blood-counts the solutions used for dilution were the 3 per cent. salt solution and the Daland's potassium-bichromate solution.

The estimation in these cases was made just before etherization, during etherization, and after recovery from the anesthetic state. Case XIII was subjected to an estimation three days before the operation, two days before the operation, one day before and just before operation, during slight anesthesia, during profound anesthesia, in the beginning of recovery, and the day after the operation. Case XXIII died of shock after the operation of gastroenterostomy, and sufficient recovery did not follow operation to permit of estimation being made. The other cases are free from complication of shock or severe hemorrhage, and afford pure instances of ether-action. Case XIII was one of examination for stricture of the rectum, a rectal bougie was passed, and there was absolutely no hemorrhage. Case XXI was one of attempted reduction of an old inguinal hernia and was uncomplicated by bleeding. Case

---

[1] As the reports of the cases are largely repetitive, it seems unnecessary to reproduce the details of each. Those chosen are Nos. I, III, XIII, XIX, XXI, XXII, and XXVII. In the reprints of the article (procurable upon application) the reports of the entire series of cases are given *in extenso*.

[2] These drawings are on file in the laboratory.

XXVII was one of breaking up of an ankylosis of the finger, and was also unaccompanied by hemorrhage. Case III does not show a reduction of hemoglobin. This apparent discrepancy arises from the estimation having been made without artificial light, and report of this case is made only to maintain scientific consistency; it can be unhesitatingly rejected from the case-group. Case XIX was an alcoholic, never completely under the influence of the ether, and examination showed no apparent fall of hemoglobin, although after etherization the hemoglobin was found diminished. This was due to too early observation, the blood being taken during a period of excitement in which there were violent struggling and tumultuous respiratory efforts.

In twenty-seven cases the fall of hemoglobin is marked and unmistakable. Each case is accompanied by a report of the physical condition of the individual and a uninary examination, with a description of the blood as examined by a Leitz $\frac{1}{12}$ oil-immersion, the slide being undiluted blood.

The following cases illustrate the effect of etherization on the blood:

CASE I.—Patient, B. B., aged eighteen years. Physical examination negative. Urine examination negative. Blood-examination before etherization: Hemoglobin 65 per cent. of normal. Red corpuscles per cubic millimeter, total, 5,000,000. Red corpuscles per cubic millimeter, normal, 3,000,000. White corpuscles per cubic millimeter, 16,500. Proportion of white to total red, 1 : 300. Proportion of white to normal red, 1 : 183. Examination of the corpuscles in the undiluted blood showed normal red, crenated red, leukocytes, and lymphocytes.

Blood-examination during etherization: Hemoglobin 60 per cent. of normal. Red corpuscles per cubic millimeter, total, 5,120,000. Red corpuscles per cubic millimeter, normal, 600,000. White corpuscles per cubic millimeter, 10,240. Proportion of white to total red, 1 : 500 Proportion of white to normal red, 1 : 58. Examination of the undiluted blood showed appearance of corpuscles normal red, macrocytes, broken-down red corpuscles, leukocytes, lymphocytes.

Blood-examination after etherization: Hemoglobin 70 per cent. of normal. Red corpuscles per cubic millimeter, total, 4,000,000. Red corpuscles per cubic millimeter, normal, 2,500,000. White corpuscles per cubic millimeter, 16,000. Proportion of white to total red, 1 : 350. Proportion of white to normal red, 1 : 156. When examined undiluted the blood showed normal red, macrocytes, crenated red corpuscles, lymphocytes, leukocytes.

CASE III.—Patient, F. McG., aged eleven years. Physical examination negative. Urine-examination negative, except that microscopic examination showed many uric-acid crystals. Blood-examination before etherization: Hemoglobin 60 per cent. of normal. Red corpuscles per cubic millimeter, total 4,200,000. Red corpuscles per cubic millimeter, normal, 4,200,000. White corpuscles per cubic millimeter, 15,000. Proportion of white to total and normal red, 1 : 280. When examined by the $\frac{1}{12}$ oil immersion the blood presented a normal appearance.

Blood-examination during etherization: Hemoglobin 62 per cent. of normal. Red corpuscles per cubic millimeter, total 5,000,000. Red corpuscles per cubic millimeter, normal, 3,000,000. White corpuscles per cubic millimeter, 15,000, Proportion of white to total red, 1 : 333. Proportion of white to normal red, 1 : 200. On examining the undiluted blood there were found present normal red poikilocytes, blood-plates, leukocytes, and lymphocytes.

Blood-examination after etherization: Hemoglobin 65 per cent. of normal. Red corpuscles per cubic millimeter, total 4,800,000. Red corpuscles per cubic millimeter, normal, 4,600,000. White corpuscles per cubic millimeter, 15,000. Proportion of white to total red, 1 : 320. Proportion of white to normal red, 1 : 306. Microscopic examination of the blood showed a few crenated corpuscles; otherwise the blood presented a normal appearance.

CASE XIII.—Patient, B. B., aged twenty-three years. Diagnosis—stricture of the rectum. Physical examination negative. Urine-examination: specific gravity, 1022; reaction, acid; no albumin; no serum-globulin; no sugar; no bile; urea, 2.1 per cent. Microscopic, amorphous urates; squamous epithelium.

Blood-examination three days before operation: Hemoglobin 80 per cent. of normal. Red corpuscles per cubic millimeter, total 5,300,000. Red corpuscles per cubic millimeter, normal, 5,300,000. White corpuscles per cubic millimeter, 10,000 Proportion of white to total red, 1 : 512. Proportion of white to normal red, 1 : 512. Examination of the undiluted blood showed normal appearance.

Blood-examination two days before operation: Hemoglobin 80 per cent. of normal. Red corpuscles per cubic millimeter, total, 5,120,000. Red corpuscles per cubic millimeter, normal, 5,120,000. White corpuscles per cubic millimeter, 10,000. Proportion of white to total and normal red, 1 : 512. Undiluted blood normal.

Blood-examination one day before operation: Hemoglobin 80 per cent. of normal. Red corpuscles per cubic millimeter, total, 5,350,000. Red corpuscles per cubic millimeter, normal, 5,350,000. White corpuscles per cubic millimeter, 10,000, Proportion of white to total and normal red, 1 : 535. Undiluted blood normal.

Blood-examination just before operation: Hemoglobin 78 per cent. of normal. Red corpuscles per cubic millimeter, total, 5,200,000. Red corpuscles per cubic millimeter, normal, 5,000,000. White corpuscles per cubic millimeter, 10,000. Proportion of white to total red, 1 : 520. Proportion of white to normal red, 1 : 500. Examination of the undiluted blood showed slight crenation of a few of the red corpuscles.

Blood-examination in early stage of etherization: Hemoglobin 72 per cent. of normal. Red corpuscles per cubic millimeter, total, 5,400,000. Red corpuscles per cubic millimeter, normal, 5,200,000. White corpuscles per cubic millimeter, 12,000. Proportion of white to total red, 1 : 480. Proportion of white to normal red, 1 : 420. Undiluted blood showed the crenation slightly more marked.

Blood-examination during profound etherization: Hemoglobin 72 per cent. of normal. Red corpuscles per cubic millimeter, total, 5,100,000. Red corpuscles per cubic millimeter, normal, 4,000,000. White corpuscles per cubic millimeter, 12,000. Proportion of white to total red, 1 : 425. Proportion of white to normal red, 1 : 316. The undiluted blood showed more marked crenation of red corpuscles.

Blood-examination after patient had fully returned to consciousness: Hemoglobin 68 per cent. of normal. Red corpuscles per cubic millimeter, total, 4,800,000. Red corpuscles per cubic millimeter, normal, 4.500,000. White corpuscles per cubic millimeter, 10,000. Proportion of white to total red, 1 : 480. Proportion of white to normal red, 1 : 450. The undiluted blood showed only slight irregularity of the red corpuscles.

Blood-examination one day after operation: Hemoglobin 70 per cent. of normal. Red corpuscles per cubic millimeter, total, 4,850,000. Red corpuscles per cubic millimeter, normal, 4,850,000. White corpuscles per cubic millimeter, 10,000. Proportion of white to total and normal red, 1 : 485. Examination of a slide of the undiluted blood showed it to be normal.

CASE XIX.—Patient, M. A. C., female, aged forty years. Physical examination negative. Urine-examination negative.

Blood-examination before etherization: Hemoglobin 54 per cent of normal. Red corpuscles per cubic millimeter, total, 6,320,000. Red corpuscles per cubic millimeter, normal, 6,000,000. White corpuscles per cubic millimeter, 12,000. Proportion of white to total red, 1 : 525. Proportion of white to normal red, 1 : 500. Microscopic examination showed only slight crenation in a few of the red corpuscles.

Blood-examination during etherization: Hemoglobin 54 per cent. of normal. Red corpuscles per cubic millimeter, total, 5,000,000. Red corpuscles per cubic millimeter, normal, 4,500,000. White corpuscles per cubic millimeter, 15,000. Proportion of white to total red, 1 : 333. Proportion of white to normal red, 1 : 300. The undiluted blood showed normal red, crenated red, and leukocytes.

Blood-examination after etherization: Hemoglobin 52 per cent. of normal. Red corpuscles per cubic millimeter, total, 5,550,000. Red corpuscles per cubic millimeter, normal, 4,300,000. White corpuscles per cubic millimeter, 15,000. Proportion of white to total red, 1 : 370. Proportion of white to normal red, 1 : 285. This showed considerable alteration, there being present normal red, microcytes, irregular red, blood-plates, and leukocytes.

CASE XXI.—Patient, D. H., male, aged fifty-one years. Physical examination negative. Urine-examination negative.

Blood-examination before etherization: Hemoglobin 80 per cent. of normal. Red corpuscles per cubic millimeter, total, 4,860,000. Red corpuscles per cubic millimeter, normal, 3,500,000. White corpuscles per cubic millimeter, 10,000. Proportion of white to total red, 1 : 486. Proportion of white to normal red, 1 : 350. The undiluted blood showed normal red, microcytes, blood-plates, leukocytes, and irregular red.

Blood-examination during etherization: Hemoglobin 70 per cent. of normal. Red corpuscles per cubic millimeter, total, 5,440,000. Red corpuscles per cubic millimeter, normal, 4,000,000. White corpuscles per cubic millimeter, 12,000. Proportion of white to total red, 1 : 452. Proportion of white to normal red, 1 : 333. Slide-examination showed normal red, crenated and irregular red, macrocytes, microcytes, and blood-plates.

Blood-examination after etherization: Hemoglobin 75 per cent. of normal. Red corpuscles per cubic millimeter, total, 5,080,000. Red corpuscles per cubic millimeter, normal, 4,500,000. White corpuscles per cubic millimeter, 10,000. Proportion of white to total red, 1 : 508. Proportion of white to normal red, 1 : 450. Microscopic examination of the blood showed normal red, polynuclear leukocytes, irregular red, and microcytes.

CASE XXII.—Patient, C. H. S., aged sixty years. Physical examination negative. Urine-examination negative.

Blood-examination before etherization: Hemoglobin 72 per cent. of normal. Red corpuscles per cubic millimeter, total, 5,120,000. Red corpuscles per cubic millimeter, normal, 4,800,000. White corpuscles per cubic millimeter, 15,000. Proportion of white to total red, 1 : 340. Proportion of white to normal red, 1 : 320. The undiluted blood showed, normal red, crenated red, granular leukocytes, and blood-plates.

Blood-examination during etherization: Hemoglobin 41 per cent. of normal. Red corpuscles per cubic millimeter, total, 5,400,000. Red corpuscles per cubic millimeter, normal, 2,500,000. White corpuscles per cubic millimeter, 15,000. Proportion of white to total red, 1 : 360. Proportion of white to normal red, 1 : 165. Microscopic examination of the undiluted blood showed normal red, markedly irregular red, microcytes, blood-plates, and leukocytes.

Blood-examination after etherization: Hemoglobin 68 per cent. of normal. Red corpuscles per cubic millimeter, total, 4,800,000. Red corpuscles per cubic millimeter, normal, 4,000,000. White corpuscles per cubic millimeter, 15,000. Proportion of white to total red, 1 : 320. Proportion of white to normal red, 1 : 266. Slides of the undiluted blood showed marked alteration, but less than during etherization.

CASE XXVII.—Patient, J. S., boy, aged fourteen years. Physical examination negative. Urine-examination negative. Blood examination before etherization: Hemoglobin 70 per cent. of normal. Red corpuscles per cubic millimeter, total, 6,168,000. Red corpuscles per cubic millimeter, normal, 5,200,000. White corpuscles per cubic millimeter, 8000. Proportion of white to total red, 1 :770. Proportion of white to normal red, 1 : 605. Slides showed slight crenation of a few of the red corpuscles.

Blood-examination during etherization: Hemoglobin 55 per cent. of normal. Red corpuscles per cubic millimeter, total, 4,456,000. Red corpuscles per cubic millimeter, normal, 2,000,000. White corpuscles per cubic millimeter, 10,000. Proportion of white to total red, 1 : 445. Proportion of white to normal red, 1 : 200. The undiluted blood showed more marked crenation of the red corpuscles.

Blood-examination after etherization: Hemoglobin 60 per cent. of normal. Red corpuscles per cubic millimeter, total, 4,696,000. Red corpuscles per cubic millimeter, normal, 2,300,000. White corpuscles per cubic millimeter, 10,000. Proportion of white to total red, 1 : 469. Proportion of white to normal red, 1 : 230. The undiluted blood showed normal red, microcytes, crenated red corpuscles, leukocytes, and blood-plates.

CONCLUSIONS.—1. Etherization produces a marked diminution in the hemoglobin of the blood.

2. The red corpuscles and the hemoglobin are especially affected in blood previously diseased, in such conditions, for instance, as anemia.

3. Irregular reports are due to faulty observation, to the presence of altered hemoglobin in the blood, to the faulty aberration as to color of a Fleischl instrument or to taking the blood before anesthesia is completed.

4. The white corpuscles show irregular changes which are not characteristic, and exhibit variations not more pronounced than would be found in the same number of samples of normal blood on different examinations.

5. Age does not apparently influence the results.

6. Ether-pneumonia may possibly be due, in some instances at least, to the action of intense cold upon the lungs, produced by the action of ether-vapor.

7. Edema of the lungs may arise from contraction of the pulmonary capillaries, thus producing a loss of *vis a tergo* and damming up of blood in the veins. Furthermore, the same condition may produce sudden paralysis of the heart.

8. The often-quoted observation as to the effect upon the hemoglobin of shock and hemorrhage re-

quires enlarged repetition upon human beings before the statements can be unreservedly accepted that hemorrhage causes a great fall in the amount of hemoglobin, but that shock does not affect it.

9. The chilling of the blood-stream may be responsible for the nephritis that occasionally follows etherization.

10. Prolonged anesthesia profoundly deteriorates the blood and strongly militates against recovery; hence rapidity of operation is most desirable.

MEDICO-CHIRURGICAL NOTES ON THE WORKS OF HIPPOCRATES AND GALEN.[1]

BY R. HARCOURT ANDERSON, M.D.,
OF NEW YORK.

BACON says: "The variable composition of man's body hath made it as an instrument easy to distemper, and therefore the poets did well to conjoin music and medicine in Apollo; because the office of medicine is but to tune this curious harp of man's body and to reduce it to harmony."

From prehistoric times there have been both the medical and surgical sick, and so many have been both the methods of treatment and the cures, and the administrators of both, that, historically speaking, this subject is chaotic and indistinct; but it is always interesting to the modern medical man to speculate on the various steps which the science has taken from the primitive state to the present.

According to Herodotus, the sick among the Babylonians and Egyptians were exposed to the passers-by, who were not only expected to diagnosticate the case, but to prescribe treatment for the same, and the various diagnoses and means of cure were collected by the priests and inscribed in sacred books or upon the pillars of the holy temples (Iamblichus). In those days the priests were the possessors of all the knowledge and learning of the Egyptians, and this was written in the forty-two Hermetic Books, and these latter were only accessible to members of the priesthood. One of the earliest mentions we have of medical literature is that Athotis, son of Menes, the ancient King of Egypt, who is reported by Manetho as the author of several works on anatomy. This was probably one of the first steps toward freedom from empiric shackles.

At this age medicine was divided into three different kinds, the pharmaceutic, dietetic, and chirurgic, and these were subdivided again and again, until we wonder how there was any practical application of healing at all. The belief was held by the early Egyptians that the body could be divided into thirty-six parts, each of which was under the particular government of one of the Decans or Aerial Demons, and according to Origen, whenever any part of the body was diseased a cure was effected by invoking the demon who presided over or governed that particular part. A kind of theologico-anatomy, according to the existing beliefs at that time, can thus be made out. Somewhat after this idea was the astrologic chart of the modern Francis Moore, which is used at the present time by believers in astrologo-theology. This assigns different anatomic regions to the influence of several special planets.

It has been said that a blind attachment to the works of great and bygone men often leads us into error, the human mind becoming trammelled; but if we look at the literature of the ancients in the proper way, that is, adapting the experience of both the old and more modern masters of science to the exigencies of the work of the present time, culling out the erroneous and false views and actions of both, will it not lead us as nearly as practical to perfection in science? It is very surprising in reading the annals of ancient surgery to find how many of the principles of our modern scientific work were laid down—principles that we follow in some cases without any modification to speak of at the present day.

Hippocrates, perhaps better than any other man, understood what the requirements of the profession were in his day, for he says: "Whoever is to acquire a competent knowledge of medicine ought to be the possessor of the following advantages—a natural disposition; instruction; a favorable position for study; early tuition; love of labor; leisure." And again he says, in another law: "Instruction in medicine is like the culture of the productions of the earth." And again: "Medicine, of all the arts, the most noble, but owing to the ignorance of those who practice it, it is at the present far behind all the other arts." The great master would probably have changed his mind had he lived in the present era; and in connection with this law of Hippocrates, I have been rather interested in finding out what a few of the more modern great men have said of the members of the healing art.

Pope says:

> They are in general the most amiable companions and the best friends and the most learned men I know.

The Rev. Dr. Parr has said:

> I have long been in the habit of reading on the medical subjects, and the great advantage I have derived from this circumstance is that I have found opportunities for conversation and friendship with a class of men whom, after a long and attentive survey of literary characters, I hold to be the most enlightened professional persons in the whole circle of human arts and sciences.

Dr. Johnson has written:

> I believe every man has found in physicians great liberality and dignity of sentiment, very prompt effusion

---

[1] Read before the New York County Medical Association, November 19, 1894.

of beneficence, and willingness to exert a lucrative art where there is no hope of lucre.

The following remark of Dr. Knox should also cause great satisfaction to the members of the profession, viz.:

> In no order are there to be found individuals better informed, more polite, humane and ingenuous than among the physicians.

REMARKS ON MYTHOLOGY.

The healing art is generally admitted to have taken its rise among the early Egyptians, although it never reached any great degree of perfection until the attention of the more cultivated Greeks was directed to it. The Egyptian Horus, son of Osiris and Isis, is the Apollo of the Greeks and also the God of Physic, and from this god Æsculapius springs. I may make the remark here that the Grecian and the Egyptian Æsculapius are not the same, and therefore not to be confounded with each other, the history of the Egyptian Æsculapius being about as cloudy as a Scotch mountain-top on a sullen day. The Greek antedates the Egyptian by about three-thousand years.

For convenience of description, medical history has been divided into epochs corresponding to four periods of the world's history. The first period corresponds to the first three-thousand years after the deluge, and during the latter part of this period we find the great names of Hippocrates, Plato, and Aristotle. After this period the most prominent physicians were the Arabians, but as far as the intrinsic value of their work is concerned it is but right to state that they were mere copyists of their predecessors, Hippocrates and Galen. They are, however, entitled to the credit of having first fully described in a classic way variola and rubeola. Indeed, so well did they do this that, excepting the etiology and consequently the treatment of these diseases, we have not learned anything further about them to the present day. During this period little or nothing was done for the advancement of science in medicine, the healing art being given up to the monks and empirics. An idea may be derived as to the status of therapeutic measures when one of the most important drugs used was a preparation of mummy dust. This was considered a very valuable remedy, and, indeed, the modern Arabians use it at the present day, mixing it with butter, forming a preparation which they call mantey. Such was the importance of this drug that a law was passed in Egypt (in the reign of Asychis) relating to the pawning of dead relatives by necessitous persons, and at another time a certain Jewish merchant of Alexandria made a fortune in "cornering" the mummy market, which at that time shipped mummy dust to the European physicians. That the ancient Egyptians knew a good deal of anatomy there can be little doubt, as, among other operations, they practised bleeding from both arteries and veins, application of the actual cautery, and also paracentesis for dropsy, *i. e.*, hydro-peritoneum. As is well known, in embalming their dead, by passing a hook through the nostrils, and by a circular movement crushing the ethmoid and sphenoid bones, they were enabled to extract through the orifice thus made not only the brain but also its membranes. In the mummy of Horseisi at the Royal College of Surgeons in London the viscera had been returned to the abdominal cavity in four distinct portions, each portion enveloped in its proper bandages. The embalmer was a kind of inferior priest or physician, and as such was reverenced and esteemed; but the dissector or cutter was not held in esteem, and immediately after he had made the incision in the side he had to run away to escape stoning by the multitude. The botanic and chemic knowledge of the Egyptians was the most valuable at that date, and it is interesting to know in connection with this that the race which was preëminent as preservers of the dead human subject do not now embalm at all. The embalming process was a very complicated one, part of which was the steeping of the body in natron for seventy days.

That mummy dust was common as a drug in the middle ages is illustrated by the following line from the "Bird in the Cage," 1633: "Make mummy of my flesh and sell me to the apothecary." The more modern Ambrose Parè mentions it as a therapeutic measure. The importance of this drug in transmitting contagious diseases must have been very great, and possibly some of our more modern diseases have as etiologic factors (by transmission), in a relative sense, the use of such drugs as mummy dust in the by-gone ages. Thus the physician of earlier times defeated his own ends. As to the origin of medicine Hippocrates says: "It was the necessity which man in the first stages of society must have felt of ascertaining the properties of vegetable productions as articles of food, which gave rise to the science of dietetics, and the discovery having been made that the same system of regimen does not apply in a disordered as in a healthy state of the body, men felt themselves compelled to study what changes of the aliment are proper in diseases." The accumulation of facts bearing on the subject gave rise to the medical art.

Hippocrates was born at Cos, one of the islands of the Archipelago, at about the eightieth Olympiad, *i. e.*, 460 B. C. He was the seventeenth lineal descendant from Æsculapius, and lived in the most advanced period of Grecian culture. He was a contemporary of Socrates and Plato, and was endowed with certain material advantages. He had a cultivated mind, and being a member of the Æsclepiæ, he possessed peculiar advantages for both theoretic and clinical study of the healing art. As there were four of the same name living about the same age, Hippocrates was called variously, "Hippocrates, the Second;" "The Great;" "The Divine Old Man," and later, "The Father of Physics;" "The Oracle of Cos," and the "Prince of Medicine."

As a writer he has given us some of the best examples of the Ionian tongue, which, however, contained certain Attic expressions. His style, although very expressive, was, like that of most of the ancients, extremely brief. After he had practised several years he cultivated the arts and sciences in travelling twelve years through the various provinces, and also in gathering information on medicines, diseases, and discoveries. We have record of his having previously studied at the famous temple of Æsculapius, in the Isle of Cos. He died at Larissa at an advanced age. Both of his sons were physicians of more or less note. To Polybus, who married his daughter, we owe the arrangement and setting forth of the famous Hippocratic records. For centuries after his death he was preëminent as an authority.

Before touching on his works perhaps it would not be out of place to mention an anecdote connected with his life. Having been called to attend the young Perdiccas, son of Alexander, King of Macedonia, who was reported to be laboring under a slow febrile disturbance, which was undermining his health, Hippocrates, observing his patient very closely, saw that when in the presence of Phila, a fair damsel of the court, he suffered considerable emotion. The diagnosis made by Hippocrates was, "a passion for Phila," and, the fair damsel not being insensible to the charms of the young prince, through the assistance of Telesphorus, the God of Recovery, the royal youngster became happy.

That Hippocrates was a most honorable man was shown by the fact that when Artaxerxes offered him large sums of money, and even entire cities, to engage him to go to Persia to relieve his armies of the plague, he sent the following reply: "Say to your master that I have ample riches; that honor will not permit me to accept his proffered gifts to render succor to the enemies of Greece." This so enraged the Persian King that he menaced the Isle of Cos with destruction unless the inhabitants would deliver up the physician, which, much to their credit, they did not do, so greatly was he esteemed. This subject has been illustrated by Girodet, and the picture presented to the Faculty of Medicine of Paris.

The people of Athens decreed a crown of gold, the right of citizenship, and a free education to the youth of Cos (as of the Athenians themselves) as a reward to Hippocrates for having stayed the plague, and one of the means of destroying this infection which he used was the building of huge fires. The Senate of Abdira sent a letter to Hippocrates to ask him to visit their renowned philosopher and scholar, Democritus, who was supposed to be affected with melancholia; but, from the description, the disease appears to have been delirium tremens.

No one thought so much of what a medical man ought to be as Hippocrates. He says, "It is the business of the physician to make new discoveries in science and to perfect such as are already made, rather than to spend his time in censuring or deprecating others;" and as he felt it to be the most excellent of all arts, this great father of physic spared not the quacks and pretenders.

As is well known, it was he who first made use of the oft-repeated quotation, viz., "That the physician ought to be the minister of nature," translating the word "minister" as servant, as it really means in the Latin. Another axiom of Hippocrates was that nature cures diseases, and he based all his methods of treatment on these lines. That he told no lies is evidenced by the quotation from Autonomus, which says that he admitted having mistaken a fracture for one of the sutures of the skull.

He was the first to cast superstition aside, and was the founder of rational medicine. In symptomatology he was well versed, and as a clinician, and on dietetics, according to his lights, he is unsurpassed to the present day.

It will perhaps not be out of place to give a copy of the original Hippocratic oath:

> "I swear by Apollo, the physician, by Æsculapius, by his daughters, Hygeia and Panacea, and by all the Gods and Goddesses, that to the best of my power and judgment I will faithfully observe this oath and obligation. The master who has instructed me in the art I will esteem as my parent and supply, as occasion may desire, with the comforts and necessaries of life. His children will I regard as my own brothers, and if they desire to learn I will instruct them in the same art without any reward or obligation. The precepts, the explanations, or whatever else belongs to the art, I will communicate to my own children, to the children of my master, and such other pupils as have subscribed to the physician's oath, and to no other person. My patients shall be treated by me to the best of my power and judgment in the most satisfactory manner without injury or violence. I will neither be prevailed upon by any other to administer pernicious physic, or to be the author of such advice myself. Cutting for the stone I will not meddle with, but leave it to the operators in that way. To whatsoever house I am sent for I will always make the patient's good the principle aim, avoiding as much as possible all voluntary injury and corruption. And whatever I hear or see in the course of a cure, or otherwise, relating to the affairs of life, nobody shall ever know it if it ought to remain a secret. May I be prosperous in life and business and forever honored and esteemed by all men as I observe this solemn oath; and may the reverse be my portion if I violate it and forswear myself."

It will be seen from the foregoing that there were specialists in surgery in the days of Hippocrates; men who did cutting for stone probably made this a special line.

On therapeutics he says:

> "As contraries cure contraries so evacuation is the remedy for repletion, and repletion is the remedy for the loss sustained by evacuation; deficiencies are to be supplied and superfluities retrenched. Contraction and relaxation are to be treated with their opposites, and fluids moving in improper courses are to be brought back unto their own channels."

Among the drugs he used were hellebore, elaterium, scammony, colocynth, mandragora, opium, etc.

That he was a skilful operator we know. He described and performed the operation for empyema, opening the chest and evacuating the pus; he was also very bold in recommending and performing trephining in fractures of the skull and for cerebral tumors. He mentions a very interesting case of caries or necrosis at the hip-joint, for which he made a large incision down to the bone and applied the actual cautery. This unfortunately was unsuccessful, tetanus supervening, and the patient dying on the eighteenth day.

His advice as to epidemics might be studied by physicians of the present day; he refers to the successful treatment of cholera by means of hellebore. In a case of hemoptysis, which was followed by pulmonary tuberculosis, the belief is stated that the former was caused by the latter, the view in fact held to-day. Concussion seems to have attracted some attention, and many are the words devoted to it; and we find a minute description of influenza, which is called epidemic cough. To Hippocrates we are indebted for auscultation, Laennec having stated that he derived most of his ideas of auscultation from Hippocrates' writings.

Gymnastics or active movement in acute diseases is condemned, and rest is advocated. Plato states that, being in ill health, he wore out first himself and afterwards many others by combining gymnastics with medicine. Hippocrates discovered the principles of derivation and revulsion in the treatment of diseases, and treated nearly all kinds of fractures and dislocations (which he had ample opportunity to study among the athletes and gladiators) by reduction and immobilization by means of waxed bandages. He gives us one of the most complete descriptions of accidents which occur at the elbow and knee-joint ever written, even at the present day.

He was very particular about the surgeon's toilet in operations, and directs that the nails should not be longer nor shorter than the ends of the fingers, and was at least cleanly in preparing for surgical work, although, perhaps, he did not go to the extreme of the modern surgeon.

In Aphorism 28 are the words: "Fumigating with aromatics promotes menstruation, and would be useful in many other cases if it did not occasion heaviness in the head," a statement that is interesting in its bearing on the use of anesthetics at that time.

The remarks on urinary sediment in the various fevers in a clinical way are good, even at the present time. The gynecologist of that day was more than primitive. Hippocrates treated cervical stenosis by dilatation with wooden or leaden tubes.

We find the records of an interesting case of a woman who had a fever and took medicine which did her no good. A hard swelling, accompanied by severe pains, occurred below the navel, which was treated by rubbing on oil with the hands, after which she had a copious discharge of blood downward and recovered. This was probably a case of ileus, as compression was resorted to for ileus at that time.

Five varieties of polypus nasi are described, and in the treatment are recommended the ligature, the knife, and the cautery; and there are also given most elaborate and extensive descriptions of accidents which occur in seventh-month and eighth-month births.

Until the days of Delpech and Stromeyer no one entertained such sound ideas on orthopedic surgery as Hippocrates. He treated club-feet by manipulation, and when human strength failed resorted to mechanical devices.

GALEN.

Claudius Galen was born in 131 A. D., at Pergamus, situated in Asia Minor (a city noted for its manufacture of parchment, from which it derived its name), and in the fifteenth year of the reign of the Emperor Adrian. He was the son of Nicon, an able and worthy architect, who gave him an ample education. In this way he became familiar with the doctrine of the Stoics, who were taught to submit the body to the mind; their passions to their reason; to consider virtue as the only good and vice as the only evil; all things external as things indifferent; the Academics, Peripatetics, and the Epicureans. He finally applied himself to the study of medicine at the famous schools of Smyrna, Corinth, and the great school of the age at Alexandria, where he studied, particularly, anatomy. Before he was twenty-one years of age he had composed some medical works. He visited Lemnos to investigate its celebrated earth, and also Syria to inspect the, at that time, renowned balsam of Syria. As far as his medical practice was concerned, he did not always tread an easy path, as many of the celebrated physicians of the day were jealous of him. His enemies taunted him as being one with theory but not practice. That he was highly esteemed by the more influential nobles of the day is evidenced by the fact that he was thought a great deal of by Bœthus, a consul whose wife he had treated successfully for fever, and be it known that in the records it is set forth that in the presence of this Boethus he made a dissection, exhibiting and demonstrating the organs of respiration and of the voice. After five years' residence in Rome he journeyed from that metropolis, and returned to his native city. This action was probably due to the persecutions that he experienced from his fellow-physicians, whom he had tried to lead back to the right path, viz., that of following the precepts and principles of Hippocrates, *i. e.*, to have them become students of nature. He was sent for by the Emperors Marcus Aurelius and Lucius Verus from Aquelliæ, but the plague breaking out they had to remove with a small retinue, Lucius Verus dying of hemorrhage on the road, and his body being sent to Rome. Galen arrived there soon after. At another time, being invited to Germany, he refused, and becoming apprehensive of foul play, retired to the house of Commodus, the Emperor's son, who was attacked by a severe fever, and was cured by Galen.

Galen's vast superiority over his colleagues was undoubted. The Princess Faustina says: "Galen shows his skill by the effects of it, while other physicians give us nothing but words." One of the first steps toward acquiring a reputation was undoubtedly the successful discovery of the royal indigestion of which he cured the Emperor, and who declared: "We have but one physician; Galen is the only man of the faculty." An idea of the royal appetite of that day may be derived when the statement is made that the Emperor Vitellius consumed in seven months food to the value of thirty-five million dollars.

Galen died in his seventieth year. He wrote not only on medicine, but on grammar, philosophy, and geometry, and it is to be regretted very much that a number of his original manuscripts were lost at the fire of the Temple of Peace at Rome. The best edition of his entire works in Greek and Latin is by Rene Chartier, published at Paris in 1679, in thirteen volumes, including also the works of Hippocrates. On the title-page of these Galen is referred to as "Archiater" (chief healer) or "Physician to the Emperor." He stands almost isolated and alone for knowledge of anatomy among the ancients, and asserts its importance as the foundation of all useful medical knowledge. It has been said that Galen could not have enjoyed the dissection of the human body, the Roman laws being very severe against those who should mutilate the bodies of the dead; but it must not be forgotten that he could have dissected the bodies of apes and of slaves and of the enemies of Rome taken in battle. Of course, his knowledge of osteology was very great, almost equivalent, indeed, to that we possess at the present day. He also had great opportunities for the study of accidents, which the gladiators (to whom he was physician) sustained during the mortal combats in which they took part.

Galen paid particular attention to hygienic remedies, such as air, food, motion, sleep, and emotion. He held that the end of medical science was to preserve the parts of which the body is composed in a state of nature, and to endeavor to reëstablish their functions when disordered, and hence the necessity of a knowledge of physiologic anatomy. The parts of the body he considered as simple or compound, similar or organic, having for their elements fire, air, earth, and water, of which the qualities are heat, moisture, dryness, and cold. While they are balanced health is maintained; when they are disturbed, disease results; and health, therefore, according to Galen, depends on the just proportion of the four elements. He admits, with Hippocrates, four humors: Blood, phelgm, yellow bile and black bile, corresponding to the four temperaments. He speaks of three kinds of spirits, natural, vital, and animal, corresponding to the same number of faculties and functions. The natural spirit he appropriates to the life in particular for the generation, growth, and nutrition of the body; the vital to the heart, for the elaboration of heat, and the animal to the head, whence proceed sensation and motion. But he denies not particular functions to particular organs, and looks upon nature as the prime factor of all, and, with Hippocrates, recommends the physician to be the minister of nature.

Galen was particularly good in prognostic acumen, and boasted not a little of it. He paid the most minute attention to symptomatology, and would probably have made a more accurate prognosis, notwithstanding his deficiency in knowledge of some of the diseases of the present day, than a great many of our so-called specialists, such was his attention to the great mistress, Nature. He paid particular attention to the reciprocal action of the heart, and to him we owe the terms used at the present day, "systole" and "diastole."

He practised surgery in the early part of his career, and writes of tumors, wounds, ulcers, fractures, dislocations, and other surgical diseases.

His physiologic experiments on living animals are good even at the present day. He described the function of the brain and nerves, maintained that sensation and volition resided in the nerves, and that through their agency the presiding principle, the soul, derives it action. He infers that the brain is the seat of this presiding principle. His ideas on the anatomy of the nerves were most erroneous, as he refers to them as tubular. He may, however, have used the term tubular (tuba, a trumpet) to demonstrate more comprehensively their transmitting power. His doctrines, without much change, were held to be correct down to the sixteenth century, Vesalius being the first to deny his views. His works are very voluminous, and comprise nearly five-hundred volumes on medicine alone. He was not a specialist in any sense of the word, being what would be called at the present time a "good all-round man," except perhaps that he was particularly learned in the nature of poisons or toxicology.

Galen treated not symptoms, but as far as possible causes. He practised phlebotomy in a very rational manner. Instead of stimulation in adynamic fevers by artificial means, he recommended a brisk rubbing of the skin until it should be hot, thereby getting the same effect from peripheral stimulation. In malaria he used pepper extensively as an antiperiodic. He frequently made the error of mistaking the pyrexia caused by some local inflammation for that of an essential fever. Clysters were used in acute enteritis, and great importance was attached to constitutional treatment in a great many apparently local diseases.

He pointed out that in the nervous system opposite causes produced somewhat similar conditions. For instance, loss of blood will produce delirium, convulsions, and paralysis, while plethora will cause apoplexy, convulsions, and paralysis. He said of epilepsy that this disease is never cured in those past the age of puberty. In pulmonary tuberculosis he used the modern "cure de lait," sending his patients to the Bay of Sorento, where they could obtain milk fresh and warm from the cow. He distinguished between the slow non-inflammatory and bronchitic form and the acute inflammatory ulcerative form, making a somewhat similar classification to that of Niemeyer of the present age.

INTESTINAL APPROXIMATION, WITH REPORT OF A CASE OF GASTRO-ENTEROSTOMY AND ONE OF END-TO-END APPROXIMATION.[1]

BY C. B. LYMAN, M.D.,
OF DENVER, COLO.;
ADJUNCT PROFESSOR OF FRACTURES AND DISLOCATIONS, MEDICAL DEPARTMENT UNIVERSITY OF DENVER; SURGEON TO UNION PACIFIC SYSTEM; VISITING SURGEON TO ST. JOSEPH'S HOSPITAL.

AT the request of your President I herewith present the report of two interesting cases in which I made use of the Murphy button for anastomotic purposes between portions of the alimentary tract. The fact that both cases resulted fatally does not deter me from reporting them, for it is from our failures that we often gain much information.

CASE I.—James G. came under my notice late in August, complaining of constipation, loss of appetite, occasional vomiting, a moderate loss of flesh, and a feeling of languor. A superficial examination revealed nothing of an organic nature. Various lines of medical treatment were used, but without improvement, and the man was sent to St. Joseph's Hospital about August 27th. When admitted to the hospital he was very much constipated; large doses of magnesium sulphate, oleum tiglii, etc., had little or no effect on him; enemata were resorted to daily to produce an evacuation; this extreme constipation continued; nausea and vomiting came on as a constant symptom; he rapidly lost flesh; he could retain nothing on his stomach but very small quantities of beef-juice. There was no rise in temperature. Examination at this time showed a stomach considerably dilated, reaching down nearly to the umbilicus; there was no pain or tenderness. The noticeable feature of the examination was the great peristaltic action of the stomach-walls; the wave of contraction could be seen beginning at the cardiac orifice and travelling slowly along the greater curvature until it reached the pylorus, where it stopped abruptly; at times the contraction assumed an hour-glass character. Upon two separate examinations I could feel at the pylorus, just as the peristaltic wave reached that point, a hard mass, ill-defined in shape and size. I made a diagnosis of tumor of the pylorus and advised an operation, which was refused by the patient and his friends. The patient was examined by a number of surgeons, among them being Dr. Hartman, of Chicago. It was agreed by all that the case was in all probability one of carcinoma of the pylorus, although some symptoms were lacking to make a perfect history; operation was advised by all.

On September 12th the patient finally agreed to the operation, and accordingly on the morning of the 13th, with the assistance of Drs. L. E. Lemen and J. W. O'Connor, I operated. I made a median incision, found a hard, nodular mass at the pylorus, extending from that point along the walls of the stomach for a distance of three inches; the duodenum was isolated with very great difficulty on account of its contracted condition. An opening was made in the duodenum at a point about opposite the entrance of the ductus communis choledochus, and one-half of a medium-sized Murphy button inserted; the other half was inserted in the stomach on the posterior surface about three inches and a half from the pylorus; the two portions of the button were then firmly pressed together. The abdominal cavity was flushed out with a normal salt-solution and the abdominal wound stitched up with silkworm-gut and the dressings applied. The man recovered from the anesthetic well, suffered no pain, and was conscious. The nausea and vomiting almost entirely ceased; the temperature became subnormal, and remained so until death took place on the fourth day, the patient being conscious to the last; the pulse ranged from 120 to 160. Nourishment was administered by the rectum after the operation, by means of beef-peptonoids, coffee, and eggs.

An autopsy was made twelve hours after death in a very great hurry; the stomach and duodenum were the only parts which were removed; the button was found in place as described; the stomach-walls were thickened to about three times their natural thickness, the mass extending from the pylorus toward the cardiac orifice, a distance of about three inches; the pyloric orifice would not admit the tip of the little finger; the stomach was considerably dilated, the duodenum contracted; there was apparently no adhesion between the walls of the stomach and duodenum at the point where the button had been inserted.

---

[1] Read before the Denver and Arapahoe Medical Society, December 11, 1894.

I have been able to find records of twenty-one cases of gastro-enterostomy done with the Murphy button. These have not all been published in detail, but have been collected in tables by various writers on this subject; to this number I would add this case, the first in this State, making twenty-two in all. Of this number twelve died, the time of death after the operation varying from a few hours to forty-six days. One died from continued hemorrhage, nine from exhaustion, one from broncho-pneumonia, one from septic peritonitis, from the fact that the tissues slipped from the grasp of the button, thus allowing the contents of the stomach and duodenum to escape into the peritoneal cavity. This would make the percentage of deaths 54.54. There have been, in all probability, other fatal cases which have not been reported, for there is a disposition among surgeons not to report their unsuccessful cases, and which if reported would swell the percentage of deaths. The results are certainly not very encouraging, and from a letter recently received from Dr. Murphy I infer that he is rather inclined to discourage operation on these cases except under the most favorable circumstances.

The operation of gastro-enterostomy is, of course, only designed for temporary relief to the distressing symptoms of nausea, vomiting, and progressive exhaustion. Unfortunately a large percentage of these patients do not give their consent to operation until the exhaustion is so far advanced that the chances for recovery from operation are small. Had this patient consented to operation at the time it was first suggested to him he might have survived.

Intestinal approximation is a subject that is being much talked about, and our journals are full of articles bearing on it. The Murphy button has come in for its share of consideration, along with the various other mechanical methods of procedure, such as the Senn plates, potato plates, Robinson's hard-rubber plates, Abbe's catgut rings, etc. It is not my purpose to discuss the comparative virtues of these various measures, since I have nothing new to offer on the subject. From my own experience I can say that the button is an ingenious device which enables us to make an anastomosis quickly, thus shortening the time of exposure of the peritoneal contents to the atmosphere, and this is an important factor in this part of the country, for it is held by many that the peritoneal membrane cannot stand exposure as long in a dry atmosphere as it can in a moist one. The operation by means of the button requires a minimum amount of manipulation of the parts for its application, and when once properly applied it is secure. When the button escapes, as it does in the course of from fourteen to twenty days, it leaves a round, clean-cut and good-sized hole, which is not liable to contract subsequently. For this particular operation of gastro-enterostomy Dr. Murphy has devised an oblong button, but I am informed that he has returned to the use of the round button.

Every surgeon can learn many things from his own operations, as well as from those of others. In my small experience in this class of cases several points have been impressed on my mind. One is that one should not undertake to operate against time; the matter of a few seconds more or less makes no material difference. In making the incision for the introduction of the button one should not make it more than two-thirds the diameter of the button; the button can be gradually worked through a small hole; one should be sure that the silk that is used for the drawstring is strong enough to stand considerable strain, and an ordinary cambric needle should be used for its introduction instead of a surgeon's needle; when the wall of the viscus is drawn up one should be certain that it is around the stem and not outside the spring, a thing that I have known to happen. One should be sure that the two portions of the button are pressed firmly, but not too firmly, together; if pressed too hard, it might cause the tissues to be cut through before adhesion had formed. There are imperfect buttons on the market; therefore every button should be carefully examined before being used; the spring should be neither too strong nor too weak, and the opposing surfaces should be broad and the spring-catch should be perfect.

CASE II.—Peter G., a Finlander and a coalminer, came to the hospital October 17th, having been injured in a coal-mine on October 14th, by having three tons of coal fall from the roof of a chamber on him while he was in a stooping posture. The great weight forced him to the floor, causing him to make what a contortionist would call a "split." When I saw him first he had a temperature of 101.5° F., and a pulse of 140; the belly was considerably swollen, tympanitic, and painful on pressure. The inner side of the left thigh and the lower portion of the abdominal wall on that side were ecchymotic and emphysematous; there was a fracture of the pelvis two inches to the left of the symphysis; a wound in the perineum two inches long communicated with the seat of fracture. The diagnosis was made of a compound fracture of the pelvis, acute peritonitis, with, probably, a perforation of the gut. The rapid development of peritonitis and symptoms of collapse, together with the presence of air in the subcutaneous tissues at the seat of the fracture, led to the supposition that a sharp spicule of bone had penetrated the parietal peritoneal membrane and had produced a perforation of the gut. Although the case offered no great encouragement for a successful operation, an operation was decided upon. With the assistance of Dr. J. W. O'Connor the abdomen was opened in the median line, the gut examined carefully, and, after a good deal of searching, a circumscribed abscess was opened on the right side midway between the crest of the ilium and the last rib; this abscess-cavity contained pus of a fecal odor, due, as I found, to a perforation in the small gut one-fourth of an inch in diameter; no other abnormal condition was found within the abdominal cavity, with the exception of a simple peritonitis. Two inches of the gut were excised and an end-to-end anastomosis was made with a large-sized Murphy button. The intestines were so distended by gas that it was impossible to replace them within the abdominal cavity without first letting some of it out; so a small incision were made and, after a large quantity of gas was allowed to escape, a stitch was introduced to close the hole. The abdominal wound was stitched up and the patient died within an hour. The autopsy revealed a fracture of the pelvis two inches from the symphysis on the left side, communicating with the perineal wound. No wound of the peritoneal membrane could be found. The retroperitoneal tissues were filled with blood; all of the intra-abdominal organs were normal except at the place where the anastomosis was made; this point was found to be in the small gut two feet from the ileo-cecal valve.

The question in this case was the origin of the perforation, whether it was produced at the time of the accident, whether the gut was contused sufficiently to cause a subsequent necrosis of the wall, or whether the perforation was the result of a preexisting pathologic condition of the intestinal wall and entirely independent of the accident? No microscopic examination was made of the section of gut which was removed, as it was unfortunately lost. There was no external, visible sign of injury on the right side where the abscess-cavity was found; the autopsy showed no solution of continuity of the peritoneal membrane. It was my belief that the perforation was the result of processes which were in existence before the accident was received. The air in the subcutaneous tissue must have been drawn in by contraction of the muscles in the immediate neighborhood.

The technique of an entero-enterostomy is very simple, and has been so many times described that I will not dwell on it at this time. I regret that both cases resulted fatally, but it is to be said in behalf of the operator that both were extreme cases, not at all suited for operation with any great hope of success. Should another case present itself for operation in the same condition as the first one I would hesitate about operating. The second case was particularly hopeless, as acute peritonitis had set in, and the heart's action was bad; there were two sources of septic infection, the abscess-cavity and the perineal wound; and finally the nationality of the patient was against success, for I find that Finlanders as a class do not stand injury and surgical shock at all well.

California Building.

THE ASIATIC LUNG-DISTOME IN THE UNITED STATES.

By HENRY B. WARD, Ph.D.,
UNIVERSITY OF NEBRASKA, LINCOLN, NEB.

In 1893 I reported[1] the occurrence of the Asiatic distome in the lungs of a cat examined in Ann Arbor, Mich. This was the first reported find of this species on this continent, and the possibility of its being a permanent guest in this country was so serious that I urged a careful examination of all cases of lung-parasites in the domestic animals, with a view to ascertaining whether this might be an isolated instance, or whether the parasite was actually established within our land, for it is true that the Chinese, among whom the parasite is very common, regard cats as great pets, and this single cat, of whose antecedents nothing was known, *might* have been brought to this country as a pet, and have wandered from its owner afterward.

In an extract[2] sent me this fall was a notice of an unknown distome found in the lungs of a dog. The description led me to suspect at once that it was *Distoma Westermanni*, and in response to my request Prof. Kellicott very kindly sent me some specimens for examination. The study of these shows beyond question their identity with the form found in Ann Arbor and with the Asiatic species. The animal from which they were taken was "a shepherd dog from the country near Columbus, Ohio." Both the host and the locality from which it came render the possibility of its having been imported from the East practically *nil*, and to my mind demonstrate the establishment of the parasite in this country.

The existence of a new human parasite within our land, and especially of one so dangerous in its home as this distome, is a matter of sufficient importance to the medical profession to call for the publication in this place of some facts concerning its anatomy and development, as well as its diagnosis and frequency, together with other biologic data, especially as references to it are wanting in most American works.

In 1880 Bälz, a European physician, reported the common occurrence of parasitic hemoptysis in

Japan, which, though ascribed to tuberculosis, was due, he thought, to a gregarine. Soon afterward he recognized the objects which he had taken for psorosperms as distome eggs, and was able to publish in 1883 a description of the parasite under the name of *Distoma pulmonale.* Later Leuckart demonstrated the identity of this form with a distome from the lung of a Bengal tiger that had died in the zoologic gardens at Amsterdam. This distome had been carefully studied and described in 1878 by Kerbert[1] under the name of *Distoma Westermanni*, which has the right of priority, and must be retained as the name of the parasite according to the established laws of zoologic nomenclature. On its presence and importance among the Eastern nations there has appeared a long list of papers largely inaccessible to the American physican. Dr. C. W. Stiles, helminthologist of the Bureau of Animal Industry at Washington, D. C., published,[2] in connection with a note on the original discovery of this parasite in the United States, a valuable bibliography of the species. The most important of these articles are those of Leuckart[3] and Yamagiwa,[4] from which, together with the papers of Kerbert and Stiles, and my own studies on the forms found in the United States, the following account was prepared.

FIG. 1.

FIG. 2.

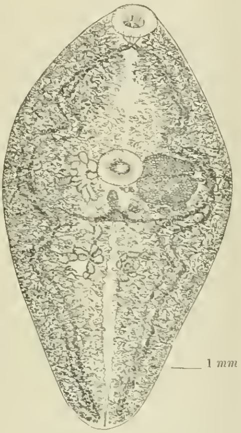

FIG. 3.

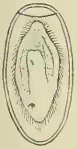

FIG. 1—*Distoma Westermanni*; ventral and lateral views (after Leuckart). Natural size.

FIG. 2.—*Distoma Westermanni* from the ventral surface. Specimen from Columbus, O., mounted in balsam. Original. Magnified 5½ times.

FIG. 3.—Egg of *D. Westermanni* with embryo. (From Leuckart after Nakahama.) Magnified 225 times.

Distoma Westermanni Kerbert 1878. Synonyms: *D. Ringeri* Cobbold, 1880. *D. pulmonis K., S.* and *Y.*, 1881. *D. pulmonale* Bälz 1883. *Mesogonimus Westermanni* Railliet 1890.

Length, 8 to 10 mm. (Leuckart); 11 to 16 mm. (Ward); 15 to 20 mm. (Kellicott.) Breadth, 4 to 6 mm. (Lkt.); 5 to 7 mm. (Wd.); 6 to 8 mm. (Kct.). The body is thick and plump, somewhat resembling a dipterous larva in shape (Fig. 1), with the posterior end more pointed than the anterior, and the ventral surface much flatter than the high arched dorsal. In color the living distome is deep-red or reddish-brown, darker along the middle of the body; the alcoholic specimen is dark steel-gray at the sides, with a brighter band along the center; the black dendritic acini (Fig. 2) of the vitelline gland can be easily recognized with a hand lens. The cuticula is everywhere covered by broad flat spines of varying length and size, which are lacking in poorly-preserved specimens.

The suckers are notably small and often difficult to see. The oral sucker has a mean diameter of 0.53 mm. (Lkt.), or 1.2 mm. (Wd.) for the American variety. It is not situated at the exact anterior extremity of the body, but is slightly subterminal, and its orifice is directed downward. The ventral sucker, or acetabulum, is a little larger than the oral, being 0.65 to 0.75 mm. in diameter (Lkt.), or smaller, 0.75 to 1 mm. (Wd.). It will be noticed that the oral was smaller in the specimens examined by Leuckart, whereas in those from Ann Arbor the reverse obtained. In the specimens from Columbus the oral suckers average 0.864 by 1.017 mm. and the ventral 1.17 by 1.31 mm., relatively the same as in the Asiatic form, but absolutely much larger. I should like to emphasize in this connection the extreme uncertainty of description based solely or even largely upon the size of organs as variable as a purely muscular sucker. Such descriptions are unfortunately very common in various quarters at present, and serve too frequently as a model for the description of new forms. For the accurate description of a species topographic relations are essential, as they are also for any identification of it subsequently. In no other way can a form be positively identified, and hence a short summary of these relations in *Distoma Westermanni* is here presented.

The general anatomy of the internal organs can easily be studied from specimens lightly stained and mounted in balsam (compare Fig. 2). Connected with the oral sucker, and lying partly at least upon it, is the prominent pharynx; it is about half as long as the diameter of the oral sucker. The esophagus, which follows directly upon the pharynx, is short, and from its end arise almost at right angles the two crura intestini, which extend in a somewhat winding course to the posterior end of the body. The clear, irregular band through the center of this part of the worm indicates the position of the excretory sinus, a longitudinal tube varying much in caliber; it is filled from numerous canals along its sides, and opens almost at the posterior tip of the body.

---

[3] Parasiten des Menschen, ii. Aufl., Bd. i, pp. 404–440.

[4] Virchow's Archiv f. pathol. Anat. u. Physiol., Bd. cxxvii, pp. 446–456.

The tissue of the body just below the surface is filled by the numerous acini of the vitellaria or yolk-glands, which impart to the lateral areas their dark, crowded appearance. These glands empty by longitudinal ducts into the two transverse ducts just behind the acetabulum. At the center, where these transverse ducts unite, is situated the vitelline reservoir. The ovary is a lobed organ at the right of the center immediately adjacent to the acetabulum; and a corresponding position on the left is taken by the condensed coils of the uterus, which are filled with yellow, thin-shelled eggs.

The testes, two in number, are located, one on either side of the excretory sinus, half-way from the acetabulum to the posterior end of the body. They are deeply-lobed organs, and are indistinct in outline in unstained specimens. Their ducts, which are not represented in Fig. 2, can be made out only with difficulty. They run obliquely toward the median side of the uterus coil, where they join and open at the common genital pore, which is situated immediately behind the acetabulum and a little to the left of the median line. There is no prominent copulatory organ in this species.

The eggs, which may be seen in enormous masses in the uterus, or found free on the surface of the worm, or in the immediate vicinity of it, are oval, yellow, and provided with a thin shell, which has a cover (Fig. 3). They measure 0.08 to 0.1 mm. in length by 0.05 mm. in breadth (Lkt.), or 0.096 to 0.118 by 0.048 to 0.055 mm. (Wd.). The oval ciliated embryo develops within the egg some time after it escapes from its host. "The fate of these embryos," says Leuckart (*loc. cit.*, p. 436), "is at present entirely unknown. That they wander directly into the later host contradicts all analogy. They will probably, as is known of other forms, next seek an intermediate host, and in this produce a generation of cercariæ, which then for the first are brought in one manner or another into a man, whether directly into the lung, as Bälz assumes, is at least questionable. Much more probable is it that the residence in that organ is the result of a further migration."

Distoma Westermanni has been found in the lungs of the tiger, cat, and dog, as well as man. The description given by Kellicott (*l. c.*, p. 3) will give a good idea of the general appearance of the infected organ. He says: "On opening the thorax the lungs were found to present unusual appearances: small brown spots were thickly distributed over the entire surface of the pleura, and scattered over the lobes were many tumor-like swellings of a deep-red color, contrasting strongly with the general pink of the lung. The tumors were mostly about the roots and along the dorsal borders of both sides. On cutting open the tumors distomes were found within; some were surrounded by a capsule, while others were burrowing after the fashion of the large distomes in the livers of sheep and cattle. These burrows were filled with débris and pus." Yamagiwa, who was a member of the Royal Japanese Commission for the investigation of the disease in that country, has given an account of the appearance of the human lung in several cases of post-mortem examination; but the general characters were the same. He also calls attention to the occasional discovery of the parasite encysted in the liver, peritoneum, mesentery, and even in the cerebral hemispheres. In the lung they appear to be confined to the periphery of the organ and inclosed in special cysts which contain not only the distomes, but also eggs and masses of Charcot's crystals. These cysts communicate with the bronchi by fine openings through which the eggs and the crystals already mentioned reach the exterior in masses of mucus and blood. The number of eggs discharged in the course of a single twenty-four hours by a patient who had suffered thirteen years from the disease was estimated to be *not less than twelve-thousand!*

Symptomatology. When in the lungs, its common abiding-place, the distome gives rise to periodic hemoptysis and chronic cough, with rusty mucoid expectoration. The condition of the patient remains good, and almost no abnormal sounds can be detected by percussion of the chest. Yamagiwa says that the general appearance of the expectorations is identical with that in tuberculosis, and, as a matter of fact, the disease was formerly diagnosticated as tuberculosis in Japan. The presence in the sputa of the eggs already described and figured is the only characteristic symptom, and positive diagnosis will rest then on the microscopic examination of the sputa, which will reveal, in case the parasite be present, numbers of its yellow-brown egg-shells. When one considers the prevalence of so-called tuberculosis in this country, and the frequently careless diagnosis of many, it is not at all unlikely that cases of this parasite may have been mistaken for tuberculosis, as Yamagiwa says was formerly the case in Japan. And this is the more probable, as the presence of such lung-parasites and the concurrent symptoms are doubtless unknown to many, and to most others are a matter of interest rather than important enough to deserve their careful attention, even though they may have heard of its occurrence in the far East.

The accidental rupture of a large bloodvessel by the destruction of the lung-tissue, and, in the severest cases, general anemia seem to be the only dangers to be feared. On removal from an infected district patients have apparently entirely recovered. During the continuance of the disease almost every patient suffers from malaise.

With regard to the region in which this parasite exists it may be said that Japan, China, Corea, and Formosa are known to be seriously infected. In one district of Japan, according to Bälz, almost every inhabitant suffered. In Formosa 15 per cent. of the entire population was infected. No doubt the disease is at home in the entire eastern portion of Asia, but exact knowledge of this region is lacking. According to the report of the Japanese Commission, those affected are largely laborers, and men rather than women.

Of the means by which the parasite reaches the lungs nothing is known, and the statement of Yamagiwa that the drinking-water is at fault rests on rather uncertain ground: the observation that in a certain town those affected drank from a single stream.

In regard to the parasite in our own country it is not necessary to emphasize the importance of immediate investigation as to the region in which it is established, and of efforts to stamp it out, or at least to keep it within its present bounds. No less important is a full knowledge of its life-history, that the means of infection may be accurately known, and by wide publicity its spread be prevented so far as is possible. For both of these ends all cases of the disease should be reported with as little delay as possible, and care should be exercised to investigate every case of lung-parasite, so that an accurate opinion as to its character may be given. In any case I shall be glad to receive specimens of suspected parasites for determination.

CLINICAL MEMORANDA.

FURTHER REPORT OF TEN CASES OF TYPHOID FEVER TREATED BY THE CHLORIN-QUININ SOLUTION,

Recommended by J. Burney Yeo, M.D., of London, England.

BY EMIL KING, M.D.,
OF FULDA, MINN.

BEING very favorably impressed by an article in the number of the *American Journal of the Medical Sciences* for June, 1894, by Dr. J. Burney Yeo, on "The Treatment of Fevers, Especially Enteric," I determined to test this treatment at the earliest opportunity. While nearly all physicians admit the success attained by the Brand bath-treatment, yet most of us cannot employ it on account of the unreasonable prejudice against it among the laity and on account of lack of facilities to give it. We must, then, employ a rational and symptomatic treatment based on the pathology of the disease.

In all of my cases but one, in which the solution was taken early in the disease and according to directions, the result was very good. In all of these cases the temperature seldom ran above 102° F., the tongue was less foul than is usual, and there was more desire for food. In none of my cases was delirium or stupor noticed. There were no complications except a relapse in one case. The good results seem to me to be due to the disinfection of the intestinal contents, consequently with less absorption of toxic material and lessened ulceration in the bowel. The antiseptics administered in this disease are legion, but all I think are inferior to chlorin, as they are not as soluble, and do not permeate the intestinal contents so thoroughly. I submit brief histories of the following ten cases.

CASE I.—J. R., a German, aged twenty-seven years, married, was by occupation a farmer. The symptoms of the disease came on gradually, and consisted of headache, coated tongue, anorexia, pain in the arms and legs, and constipation. I saw him for the first time on September 19th, on the sixth day of his illness. In addition to the foregoing symptoms his temperature was 103°, and he had pain on pressure in the right iliac and umbilical regions, with sleeplessness. Treatment was as follows: rest in bed, a diet of diluted milk and beef-broth, cold and wet applications to the head, calomel and sodium bicarbonate in small doses until the bowels moved freely, and then the chlorin and quinin solution, a tablespoonful diluted in water, was given every two hours. The temperature never rose above 102° F. The disease ran a mild course, and convalescence began at the end of the third week of illness. Recovery was rapid.

CASE II.—M. B., a female, a German, aged twenty years, was a farmer's wife. The symptoms came on gradually, and consisted of headache, sleeplessness, anorexia, a heavily coated tongue, diarrhea, and pain in the back, arms, legs, and, on pressure, in the right iliac region. I saw the woman for the first time on September 20th, on the eighth day of her illness. I found a temperature of 103.7° F., and on pressure gurgling and tenderness in the right iliac fossa. Treatment consisted in a diet of diluted milk, water, weak lemonade without sugar, and weak tea, powdered opium and bismuth subnitrate until the diarrhea lessened, and of the chlorin-quinin solution a tablespoonful every two hours. The fever subsided, headache and pains lessened, but the vertigo continued into convalescence. A slight bronchitis developed, which however subsided without treatment. Convalescence began on October 3d, and continued without interruption.

CASE III.—A. G., a German, male, aged twenty-nine years, single, was by occupation a merchant. Symptoms began gradually, and consisted in weariness, anorexia, a heavily coated tongue, and very foul breath, thirst, slight diarrhea, and pain in the abdomen. I saw the patient for the first time on September 20th, on the fourth day of his illness. In addition to the symptoms noted he had a temperature of 103.5°. He was ordered rest in bed, a milk-diet, water to drink, opium for the diarrhea, and of the chlorin-quinin solution a tablespoonful every two hours. Convalescence began on the eighteenth day of his illness, resulting in rapid recovery.

CASE IV.—W. W., a male, an American, aged twenty-four years, married, was by occupation a surveyor. The symptoms developed gradually, with anorexia, a coated tongue, thirst, pains in the arms, legs, and iliac region, constipation, slight tympanites, and sleeplessness. I saw him for the first time on September 23d, on the seventh day of his illness. The temperature was 104°. I ordered absolute rest in bed, a milk-diet, calomel, and sodium bicarbonate in small doses until the bowels moved freely, and of the chlorin-quinin solution a tablespoonful every two hours. A cold pack was applied once or twice during the night for a week, with very good results. From the fourteenth day the temperature never went above 102°. Convalescence was established on the twentieth day, and continued without interruption.

CASE V.—F. B., a German, male, aged twenty-five years, a farmer, married, had symptoms which came on gradually and consisted of headache, anorexia, a coated tongue, thirst, constipation, and slight tenderness in the right iliac region. I saw him for the first time on September 23d, which was the third day of his illness. His temperature at this time was 103.4°. I ordered rest in bed and a diet as in the preceding cases. His headache being very severe, I ordered a few doses of Dover's powder, also cold and wet applications to the head. The chlorin and quinin solution, a tablespoonful, was ordered every two hours. The case ran a mild course, convalescence being established early in the fourth week and continuing favorably.

CASE VI.—W. P., of German parentage, a male, aged twenty-three years, single, was a brother of Case V. The symptoms in this case were very much like those of Case V except that there were more sleeplessness, a higher temperature (104°), and a severe bronchitis with threatened pneumonia, of which he had a severe attack two years ago, but which readily yielded to prompt treatment with tincture of veratrum viride, and sharp counter-irritation. The chlorin and quinin-solution was given as in the preceding cases. Convalescence began on the twenty-fourth day. He was exceedingly weak, and brandy was ordered, this being the only case in which alcoholic stimulants were found necessary. Recovery was somewhat slow.

CASE VII.—J. P., of German parentage, a male, aged twenty years, single, a farmer, had symptoms beginning with headache, pains in the arms, legs, and back, a coated tongue, anorexia, and sleeplessness. I first saw him on October 2d, on the third day of his illness, when the temperature was 102.3°, and slight tenderness on pressure in the right iliac fossa. The treatment was the same as in the former cases. The disease ran a very favorable course, convalescence being established by the seventeenth day, the appetite returning rapidly, and recovery was prompt.

CASE VIII.—M. P., a female, German, married, and mother of twelve children, aged fifty-three years, was in a bad physical condition through constant nursing and the care of a large family. The disease came on gradually with vertigo, headache, pains in the back, coated tongue, and anorexia. I saw her for the first time on October 6th, on the fourth day of her illness. The temperature was 104°, there were some tympanites and much tenderness in the abdomen. The treatment in this case varied in the omission of the quinin, which caused severe tinnitus. The duration of the illness was four weeks, convalescence being somewhat protracted but finally complete.

CASES IX and X.—C. H. and M. H., brother and sister, of German parentage, aged twelve and fourteen years respectively, in whom the disease came on at the same time and gradually, the symptoms consisting of weariness, coated tongue, and anorexia, with a tendency to drowsiness. I saw them for the first time on October 8th, on the seventh day of their illness. The boy had a temperature of 104°, the girl 103.2°. Both had pain in the abdomen on pressure. There were constipation and tympanites in both. I ordered rest in bed (having found them sitting up), milk-diet, calomel, and sodium bicarbonate in small doses to move the bowels, cold and wet applications to the head, orders to give a cold pack and sponging being refused by the parents. The solution of chlorin and quinin, a dessertspoonful, was ordered every two hours and diluted with water. Convalescence began on the twenty-third day of the illness, resulting in perfect recoveries.

I could lengthen this clinical report by adding five more cases successfully treated by this method. Only one of the entire number of cases had a relapse, and this case has now perfectly recovered. I hope that this treatment will be given a thorough trial in some hospital, and I firmly believe that the results, when the treatment begins early, will be as good as those obtained by the Brand method.

PRIMARY LARYNGEAL DIPHTHERIA SUCCESSFULLY TREATED WITH DIVIDED DOSES OF BEHRING'S ANTITOXIN NO. 1.[1]

BY H. H. FREUND, M.D.,
OF PHILADELPHIA.

THE patient was a male child one year old, weighing 15 pounds, seen on the evening of December 14, 1894, at 6 P.M., with a history of having been croupy, restless, feverish, and breathing rapidly for the previous twenty-four hours. Examination of the fauces revealed an intense redness of the pharynx; and surrounding the rima glottidis the characteristic appearance of the diphtheric membrane was evident at this examination. No fetor could be detected in the breath, nor was any lymphatic glandular enlargement present. At the first examination the pulse was 136, the temperature 99°, and the respiration 26. Six hours later, 4 c.c. (♏ 64) of Behring's antitoxin were injected in the scapular region, slight massage soon dispelling the swelling. Eight hours after the first injection of antitoxin the pulse was 160, the temperature 101.4°, and the respirations 40. The little patient was restless during the night, and on the following day no marked improvement could be detected in its condition. The dipththeric membrane had extended upward into the posterior wall of the pharynx as much as a half-inch. Twenty-four hours after the first injection, a second one was given to the amount of 3 c.c. (♏ 48) near the site of the first injection. During the second night the child was easier, the whole condition took a more favorable turn. On the morning of the second day the pulse was 126, the temperature 100.2°, and the respirations 28. At the end of the second day, the third and last injection, consisting of 3 c.c. (♏ 48), was made near the site of the other two injections. On the morning of the third day the nurse reported that the child had had a good night, taking nourishment well and sleeping quietly. Examination revealed a total disappearance of all visual diphtheric deposit.

---

[1] Read before The James Aitken Meigs Medical Association.

The fever-chart in this case does not show a decided drop in the temperature after the injections, which corresponds with the observations of others who have used this form of treatment.

During the period dating from the use of the first injection to that of the last, forty-eight hours had elapsed, and in this time other systemic and local treatment had been used, consisting of divided doses of calomel, salol, and a mixture of seneg, ipecac, tincture of nux vomica, ammonium carbonate, with the use of a fine stream of hydrogen dioxid directed against the larynx. This plan of using the hydrogen dioxid proved more efficacious than when used with an atomizer Mercurial inunctions were also used about the neck. The child was still at the breast. Large doses of whiskey were administered at frequent intervals. No lung-complications or kidney-complications were present. Although this case may be said to have had the benefit of a mixed treatment, yet, when we take into consideration the rapidly fatal termination of this form of diphtheria, and remember that in sixty hours from the time of the first injection the child was completely out of all danger, it speaks volumes for the antitoxin-treatment. Physicians who have seen much diphtheria know of the fatality accompanying the laryngeal form, and will appreciate the fact that the patient did well with this treatment.

In consultation with Dr. Edwin Rosenthal we decided to use Behring's Fluid, No. 1, in divided doses, which was contrary to the rules of Dr. Behring's practice; yet the good and prompt results obtained by this method justified us in our procedure. On the evening of our first visit the laryngeal stenosis was so marked and threatening to the child's life that it was a question whether we should use antitoxin or intubate; but having such a powerful remedy at hand, and knowing that the Behring fluid was particularly indicated in the laryngeal form of diphtheria, we felt greatly assured of ultimate success. Sixty hours after the first injection all laryngeal complications were removed. I am indebted to Dr. Edwin Rosenthal for his wise counsel and his kindness in furnishing the antitoxin.

Dr. A. Klein performed the necessary bacteriologic examinations, and reports that the specimens taken from the child showed immense numbers of the diphtheric bacilli, with nests of streptococci and staphylococci. To him, also, I express my thanks for his painstaking labors.

Since writing the foregoing report I have had two more cases of laryngeal diphtheria which have recovered. The first was that of a female child, four years old. The characteristic picture of stenosis of the larynx was very marked thirty-six hours after the use of Behring's Antitoxin No. 2. A marked improvement in the case took place, although later on pneumonia developed, from which, however, the child made complete recovery.

The second case was that of a male child, eighteen months old. Behring's Antitoxin No. 2 was injected. Twenty-four hours later the membranes began to disintegrate and became loosened to such an extent that asphyxia was imminent. Intubation was practised, with immediate relief. Twenty-one hours later the tube was coughed away, and from then on the child has made an uninterrupted recovery. In the last two cases no other treatment was used.

A CASE RESEMBLING MULTIPLE SCLEROSIS FOLLOWING AN INJURY TO THE SKULL IN WHICH THERE WAS FRACTURE WITH MARKED DEPRESSION.

By HAROLD N. MOYER, M.D.,
OF CHICAGO,
CHIEF OF NEUROLOGICAL CLINIC RUSH MEDICAL COLLEGE, SERVICE OF PROFESSOR LYMAN.

The following case presents a rather anomalous picture, and one that hitherto in my experience has not occurred. S. C., a tailor, forty-five years of age, a Bohemian, with a negative family history, stated that his previous health-history has been good, and he denies venereal infection. Seventeen months ago he received a severe injury to the head, which rendered him unconscious for half an hour. He was five weeks in the hospital, and at the end of that time he was so far recovered that he made an effort to resume his occupation, but he had to give it up, owing to a rapidly increasing tremor of the right hand. Of late this has become much more marked, and with it has developed a weakness of the entire right side. There has been some pain in the right arm and through the chest. The patient calls this rheumatism, and it is for that which he seeks relief.

On the left side of the head, extending nearly to the middle line just in front of a vertical line drawn through the external auditory meatus, is an irregular depression in the skull, about one-and-one-half inches in diameter, and of a depth of from one-half to three-fourths of an inch. There is a marked tremor in the right hand, at first fine, then becoming coarse, which is aggravated by grasping objects or attempting to make voluntary movements. As a rule, when the patient is at rest there is no movement of the hand. There is apparently a slight tremor in the right leg and also of the head; but one is not quite sure if these are not transmitted from the arm. The pupils and fields of vision are normal. There is no static ataxia, no nystagmus, and no impairment of speech. Strength in the right arm is diminished one-half as compared with the left. It is impossible to determine accurately the condition of the deep reflexes because of the inability of the patient to relax the muscles. Sensation is quite normal on both the right and left sides. The patient, who is decidedly deficient in intelligence, says that he has had a tremor of the right hand for the past eighteen years, but that it was not sufficient to impair his usefulness in his occupation until after the reception of the injury and fracture of the skull described. I am inclined, from all the circumstances of the case, to think that the patient before the injury might have been slightly neurasthenic, and that this accounted for the tremor of which he speaks. Certainly since the accident he has been unable to follow his occupation.

The development of an intention-tremor after a head-injury has come under my observation only once, and in that case it was not associated with skull-fracture. It is certainly interesting to speculate as to what might have been the changes in the brain and membranes that could have given rise to the particular symptoms that we have in this case. It is also unfortunate that the want of intelligence on the part of the patient renders the clinical history somewhat obscure, and also that the condition of the deep reflexes could not be accurately determined. To my mind the most interesting feature of the case is the development of the tremor shortly after the fracture of the skull, which seemed to initiate a degenerative process closely allied in its clinical manifestations to the ordinary form of disseminated sclerosis. The fracture and depression of the skull are too far forward to bring them in direct relation with the motor area of the cortex, especially that which supplies the right arm, where the tremor first developed. There is nothing to militate against the view of an extension from the original point of a meningeal inflammation which would involve the entire motor region on the left side of the brain. In these cases, however, we should rather look for paralysis and contracture, such as follow the ordinary forms of pachymeningitis. The tremor and subsequent paralysis speak rather for a degeneration of the nerve-cells or some interruption in the conductivity of the fibers leading from the motor region.

A post-mortem examination alone would settle the exact nature of the pathologic changes underlying this case. The rarity of the clinical picture must be my excuse for presenting a somewhat fragmentary observation.

NOTES UPON A CASE OF PERFORATION OF THE UTERUS DURING CURETTAGE.

BY J. W. HICKMAN, M.D.,
OF TACOMA, WASHINGTON.

A SHORT time ago, prior to repairing a lacerated cervix, assisted by Dr. Yocom, I performed preliminary curetting, as is my custom in most cases of the kind. After scraping the endometrium with a dull curet, I introduced a sharp curet, and went over the surface again rather lightly. Then I inserted the uterine douche-tube, and in pushing it up with but a trifle of force, merely enough to be sure I was reaching every part of the fundus, it slipped through into the peritoneal cavity and was withdrawn rather quickly. At the time I was using a 1 per-cent. solution of creolin in sterilized water, and my judgment is that perhaps half an ounce, or rather less, of the fluid had time to escape into the belly. After my tube slipped up fully two inches farther than what seemed to me to be the fundus I introduced a uterine sound to be absolutely sure that I had perforated the uterine wall. I was then abundantly satisfied of what I had done. I did not irrigate the uterine cavity again, but immediately proceeded with the repair of the cervix. Upon paring away the desired amount of tissue the hemorrhage was extraordinarily profuse, and I was obliged on this account to insert the sutures upon one side before preparing the other. The cervix was very soft, so soft, indeed, that the needle passed through as easily as it would through skin and muscle.

I have curetted perhaps several hundred times, and I have rarely done a curettage more lightly; indeed I did most of the work with a dull curet. Another point is, that I did not perforate with the curet, but with the tube of the irrigator. I was afterward comforted by the fact that I had prepared my instruments and hands with scrupulous care, and that I had so far as is possible rendered the vagina aseptic. In spite of all this, I must acknowledge I suffered considerable mental shock during the remaining part of the operation. The patient recovered without an unpleasant symptom of any note. There was no acceleration of pulse or rise of temperature; simply a moderate amount of soreness over the right side of the abdomen over the seat of perforation. Even this subsided within forty-eight hours. This uterus was no doubt unusually thin-walled, likely thinner at some points than others, and, from the condition of the cervix, was certainly abnormally soft. The operation was done three months after the last delivery.

This case illustrates the fact that uterine perforation during curettage is a possible accident. In the future I shall curet no less frequently, no less thoroughly. I shall, however, be more careful than ever, if possible, to be clean, so that if the accident shall be repeated no septic material will be carried into the abdominal cavity.

In reporting this case I am simply carrying out my conviction that not merely successes alone should be reported, but accidents and failures as well. In no other way can we get at the whole truth regarding any line of surgical work.

MEDICAL PROGRESS.

Fibromyomatous Change in the Bladder.—MONRO (*Journal of Pathology and Bacteriology*, vol. iii, No. 1, p. 144) has reported the case of a commercial traveller, twenty-nine years old, who complained of pain and difficulty in micturition. From early life he had had to strain while emptying his bladder. Ten years before coming under observation he had a slight illness, supposed to be due to hepatic disturbance, associated with high color of the urine, which threw down a sediment on standing. Some time later he suffered an injury of the left buttock. For two years there had been complaint of severe pain in the left lumbar region, passing downward to the left groin and testicle, and accompanied by sickness and vomiting. These symptoms would pass off after two or three days, to recur after an interval varying from ten days to a month. In the early part of the illness clotted blood was observed to be present in the urine for two or three days. A hard, tender swelling, dull upon percussion, was found in the lower part of the abdomen. There was also a sense of tumefaction in the left lumbar and iliac regions, and at the upper part of this swelling there was felt a hard, egg-shaped body which could be rolled under the fingers. Another and more superficial body was detected in the same neighborhood. The urine was decomposing and contained much albumin, but no tube-casts or blood-corpuscles were detected. There was no difficulty in passing an instrument into the bladder. An operation was undertaken for the relief of the symptoms, in the course of which it was deemed advisable to excise the bladder. The procedure was a tedious one, as the ureters were so much dilated as to resemble small intestines, and when they were cut across they poured out a huge volume of urine into the wound. The patient died five hours afterward. Upon post-mortem examination the bladder was found to be greatly enlarged and its wall much thickened. The inner surface suggested the appearance of a lobulated kidney, but the lobules were irregular in shape and size, some being very large. The intervening depressions were almost half an inch deep; one situated to the left of the trigone reached to a depth of more than an inch and a half. The surface of the lobules was reddish-brown in color, with a tint of blue, but presented numerous white patches, consisting of easily detachable flakes of epithelium. On microscopic examination the lobules or elevations of the mucous surface were found to consist of unstriped muscle and of connective-tissue elements. There was, moreover, an abundant infiltration of round cells, which at some parts were collected in such numbers as to suggest the commencement of small abscesses. Upon the upper end of the bladder were certain bodies that to the naked eye presented the appearance of convoluted rolls or worms imbedded in fibrous tissue. Microscopically these were found to consist largely of unstriped muscular fibers, together with fibrous tissue and numerous capillaries. The kidneys and ureters were such as are seen in fully developed hydronephrosis. The left kidney was eight and the right six inches in length. On the left side two ureters passed down from the kidney to the bladder. These were at first quite separate, but they became united to one another halfway down, though the lumen of each remained distinct from that of the other throughout its whole length, and the two opened by separate orifices into the bladder. The right ureter was single. All three ureters were much dilated, and measured while lying flat more than an inch and a half across. Connected with the pelvis were two isolated tumors that proved to be typical hard fibromata. They measured about two or three inches in length respectively. Each was ovoid in form, with a distinct capsule, and varied in hardness in different parts.

Successful Operation in Three Cases of Intra-cranial Abscess.—MURRAY (*British Medical Journal*, No. 1775, p. 9) has reported three cases of intra-cranial abscess in which relief was afforded by surgical interference. One of these has been previously reported (see THE MEDICAL NEWS, March 26, 1892, p. 352). During the three-and-a-half years that have elapsed since the operation, the patient has had no convulsions, enjoying good health, and presenting no signs of mental impairment.

The second case occurred in a girl, nine-and-a-half years old, in which symptoms of abscess of the brain developed in the sequence of suppurative inflammation of the middle ear. A disc of bone was removed with a half-inch trephine about three-quarters of an inch directly above the external auditory meatus upon the left side. The dura mater bulged into the opening and did not pulsate. When the dura was divided the brain protruded through the incision. A tenotomy-knife was then passed into the brain for about half an inch, when it entered an abscess-cavity in the temporo-sphenoidal lobe, and pus at once escaped. On further dilating the opening with a pair of sinus-forceps the pus was forcibly ejected. A drainage-tube was inserted, and the abscess-cavity thoroughly cleansed by syringing with warm boric-acid solution. The flap was sutured, and the drainage-tube brought to the surface through an opening made in the middle flap. Three ounces of pus were collected and fully half an ounce was lost. The immediate effect of the operation was very marked. The pulse, which had been 48, rose to 72, and the respiration, which had been 8, rose to 28. Two weeks later the mastoid antrum was opened and unhealthy granulation-tissue removed. During a year following the operation the child was perfectly well.

The third case occurred in a boy, eleven years old, who had had a discharge from the right ear for three weeks, with headache, vomiting, elevation of temperature, and double optic neuritis. An incision over the mastoid process exposed a subperiosteal abscess. In the failure of improvement the mastoid antrum was shortly afterward opened, and offensive granulation-tissue removed. An extra-dural abscess was found in the lateral sinus, from which about a dram of thick, offensive pus was evacuated. The sinus, covered with granulation-tissue, was collapsed and appeared to be thrombosed, and was not opened. Relief still did not ensue. It was now decided to explore the cerebellum from the seat of previous operation. On incising the dura the brain protruded, and by passing a director into the cerebellum forward and inward an abscess was opened, and from four to six drams of sweet pus escaped. The cavity was well washed out through a drainage-tube. which was brought to the surface through an opening made in the middle of the flap. The pulse rose from 20 to 100 beats per minute, and the temperature from 97° to 99.6°. Recovery was thereafter uninterrupted.

Post-neuritic Atrophy with Peculiar Iris-Reaction.—At the Eighth International Ophthalmological Congress recently held at Edinburgh GOULD reported the case of a girl, twelve years old, who had had some obscure spinal and cerebral disease and presented complete blindness, stabile mydriasis, and most intense neuro-retinitis, both papillæ being enormously swollen, the retinal vessels congested and tortuous, and often hidden by the inflamed retina and by multiple scattered hemorrhages. Six months later the neuro-retinitis had quieted down, and typical optic atrophy was pronounced, though vestiges of inflammation remained. Perception of light was absent. After the lapse of a further six months there was absolute optic atrophy of the typical white variety and stabile mydriasis, so far as related to the stimulus of artificial light, and complete blindness. The most brilliant and concentrated light thrown suddenly or continuously on the pupil failed to elicit iris-reaction or perception-response. By seating the child before an open window, however, the street in front being illumined by sunlight or diffused daylight, the pupils were found within half a minute or more to be of normal size. The parents had also noticed that when the child played out of doors the pupils were of the size usual in other people. The motion of the contraction was too slow for observation—that is, one could not positively say that the myotic movement was taking place by watching the pupils attentively. In the same way, the widening, when the patient's face was turned away from the window and directed toward a moderately lighted room, was perhaps more rapid, but still too slow for the detection of its progression.

THERAPEUTIC NOTES.

The Treatment of Empyema in Children.—At a recent meeting of the Medical Society of London CAUTLEY (*Lancet*, No. 3727, p. 285) reported the results of an analysis of a series of eighty-four cases of empyema in children with a mortality of 16.6 per cent. Of twelve cases treated by aspiration only one died, one ruptured externally, and one discharged through the lung. Of thirty-five treated by incision and drainage seven died, while of thirty-three treated by resection and drainage six died. Five out of six cases under two years of age treated by resection died. In the large proportion of the fatal cases death was not due to anything connected with the wound. While it was admitted to be possible for small effusions to be absorbed, it was most emphatically asserted that in cases in which pus was present the only sound treatment was its evacuation. Aspiration sometimes proved useful, and might effect a cure in cases in which the pneumococcus was the primary cause. The disadvantage of aspiration was that thick effusions would not pass through the canula, and that it was impossible to remove all of the contents of the cavity, thus leaving behind a focus of irritation, and that pus rapidly reaccumulated afterward. Moreover, there were certain dangers if the operation was performed too rapidly. On the other hand, aspiration is useful in cases of urgency, in those in which the fluid is thin and sero-purulent, and in cases of double empyema. The advantages of resection are better drainage and facility for exploring the boundaries of the cavity, and for breaking down adhesions. There is also less danger of hemorrhage, and the chances of recovery are better, while recovery is more rapid. The disadvantages of resection are that it is more severe, and, judging from the mortality, ought never to be employed in children under two years of age, and there seems, also, to be greater liability to pyemia and deformity of the chest. It ought, therefore, only to be had recourse to in cases in which the tube cannot be inserted without it, and when drainage is imperfect or for the cure of an old sinus. The tube should be short, and only left in place for a short time. Empyemata do not heal by granulation from the bottom, but by expansion of the lung, ascent of the diaphragm, and contraction of the chest-wall. The tube should always be removed as soon as the discharge becomes more serous and scanty. If left in longer, it becomes a source of irritation.

Treatment of Chorea Minor With Static Electricity.—BROWER (*North American Practitioner*, vol. vii, No. 2, p. 61) has obtained satisfactory results in the treatment of eighty-eight cases of chorea minor with static electricity in conjunction with such other medication as seemed indicated in each particular case. The patient is placed upon an insulated stool, usually connected with the positive pole, and over his head is suspended a coronet with sharp points connected with the other pole. Insulation with a direct current is thus continued for about ten minutes. The patient is then subjected for about five minutes to the static breeze, using for this purpose the induced current. After the treatment is completed the patient is advised to sit quietly for about ten minutes. If possible, the treatment is repeated every day for the first week, then three times during the second week, and afterward twice a week until recovery ensues.

A machine having not less than four plates of twenty-six or twenty-eight inches in diameter is necessary.

The cases were, besides, placed under the best possible hygienic conditions. When necessary, and this was the rule, school was stopped, an hour of rest required in a darkened room at mid-day, the diet carefully regulated, and elimination by the bowels, skin, and kidneys maintained at a proper standard. Arsenic in some form and in varying amounts was administered to all, and in the most rebellious cases was pushed to its physiologic limit. Iron was given when the hemoglobin was found to be below the normal, Blaud's mass being preferred. In females with delayed puberty cimicifuga was prescribed. When there was a rheumatic history sodium salicylate or salophen was made a part of the treatment. If sleep was insufficient, sodium bromid was administered at bedtime, with or without chloral, as seemed to be necessary. The acute cases—that is, those in which the symptoms had continued for less than a month, yielded to treatment in four weeks; in the remainder the average duration was between twelve and eighteen weeks.

Ethyl Bromid as an Anesthetic in Oto-laryngologic Practice.—In a paper read before the Louisiana State Medical Society DE ROALDES had a commendatory word to say for the employment of ethyl bromid as an anesthetic in oto-laryngologic practice, particularly among children. He had successfully employed the agent for this purpose in 150 cases in the course of two years. In effecting anesthesia the agent is poured in large quantity (from one dram to two-and-a-half drams) upon an Esmarch mask, which is closely applied over the nose and mouth with a view to excluding the air. Narcosis is induced in the course of from thirty seconds to two or three minutes, and is sufficiently prolonged to permit of the performance of many short operations. Should sensibility return before the operation is completed, a few more inhalations of the anesthetic may be permitted. The advantages claimed for ethyl bromid are its rapidity of action; the short period of excitement attending its use; the induction at times of complete analgesia, with comparative integrity of the mental faculties; the rapidity with which the nacrotic effects pass off; the uninviting character of the vapor; the relative absence of unpleasant after-effects; the absence of any undesirable influence upon pulse and respiration; its portability as compared with nitrous-oxid gas.

Sodium Salicylate for Exophthalmic Goiter.—CHIBRET (*Revue Générale d'Ophthalmologie*, 1895, No. 1, p. 1) has employed sodium salicylate in the treatment of four cases of exophthalmic goiter with satisfactory results. He administered seventy-five grains in four equal parts, freely diluted with water, in the course of the twenty-four hours.

SATURDAY, MARCH 2, 1895.

THE SURGERY OF THE PERICARDIUM.

MODERN antisepsis has contributed largely to the establishment of well-defined surgical principles, deviation from which is only exceptionally necessary, and then only under exceptional conditions.

We have learned that certain definite lesions and morbid states, whether situated on the surface of the body or within any of its cavities, require equally certain and definite operative measures for their relief. Thus there is but one remedy for hemorrhage (ligation), but one for purulent accumulations (evacuation), but one for malignant neoplasms (excision), but one for aneurysm (occlusion), though there may be more than one mode of applying the remedy.

These remarks are prompted by the report of a series of successful operations upon the pericardium at the hands of different operators, and only recently[1] we took occasion to comment upon a case in which the performance of cardicentesis was followed by recovery. The possibility of successful surgical intervention for the relief of wounds of the heart has been suggested,[2] and as a matter of fact a case is on record[1] in which such relief was afforded in a case of incised wound of the heart.

The recent cases to which we have referred include one of suture of an incised pericardium, one of purulent pericarditis with repeated puncture followed by free incision, and one of repeated paracentesis pericardii. The first case is reported by DALTON,[2] and occurred in a man, twenty-two years old, who received a stab in the left breast, half an inch long and an inch-and-a-half above the left nipple, with little hemorrhage. There were faintness and nausea, but no abnormal physical signs. The wound was cleansed and a dressing of antiseptic gauze applied. In a short time the temperature began to rise, the pulse became accelerated, and the respiration to increase in frequency. Dulness was now manifest upon the entire left side of the chest, and there was complaint of considerable pain. Upon the removal of the dressing applied, blood and air gushed from the wound with each respiration. An incision, eight inches long, was made over and parallel to the fourth rib, six inches of which were resected. A bleeding intercostal artery was found and tied. The pleural cavity was filled with clotted and fluid blood, which was removed by turning the patient upon his left side and using a long pair of forceps armed with a sponge. When the patient was placed upon his back and the margins of the wound separated by strong retractors, a wound of the pericardium, two inches in length, was revealed. At the inner angle of the wound the pericardium was penetrated to the extent of half an inch; the remainder of the wound failed to penetrate the pericardial cavity. By means of two pairs of long forceps and with the aid of a long needle-holder armed with a sharply curved needle and catgut, the pericardial wound was with great difficulty closed by a continuous suture. The pleural cavity was thoroughly irrigated with hot sterilized water, the surgical wound closed and covered by an antiseptic dressing, a cotton bandage and a crinoline bandage, without drainage. The pericardial sac contained only the usual amount of fluid. The patient made an uninterrupted and rapid recovery.

The second case is reported by EISELSBERG,[3] and occurred in a lad, seventeen years old, who received a wound in the pericardium, penetrating perhaps an inch. There was little bleeding, and consciousness was preserved. The wound healed without complication, and the patient was soon able to resume his work. In the course of a month, however, his health began to fail. He tired readily, appeared feverish, and suffered with dyspnea. In the course of two months more the feet became swollen, and the boy sought professional advice. He presented dyspnea, cyanosis of the lips, a frequent and arhythmic pulse, and edema of the lower extremities. The remains of the former wound were visible at the level of and two-fingers' breadth external to the left nipple. On percussion a triangular area of dulness was made out, with its right border corresponding to the right sternal margin, the left beginning at the left sternal margin at the level of the second rib and passing obliquely downward to a point about two-fingers' breadth external to the left nipple. The pulmonary percussion-note was resonant, the dulness upon the right side posteriorly beginning a little higher than upon the left. The breath-sounds were normal, except for occasional mucous râles. The heart-sounds were inaudible; nor could a friction-sound be detected. The abdomen was somewhat distended. The liver was distinctly enlarged and hard. The urine contained excessive urates, but no alubmin. There were moderate elevation of the evening temperature and considerable cough.

It was recognized that an accumulation of fluid was present in the pericardium, and for its evacuation a trocar was introduced just to the left of the sternum in the fifth interspace, giving exit to a quart of thin, purulent fluid. Distinct relief was temporarily afforded, but in the course of two weeks the puncture had to be repeated, this time evacuating slightly less fluid, and after the lapse of another week a third puncture was necessary, evacuating rather more than a quart of purulent matter. The improvement, however, was again but temporary, and resection of the fourth costal cartilage, with incision of the pericardium, evacuation of its contents and irrigation with a warm solution of salicylic acid, was practised. To prevent contamination of neighboring parts the margins of the incision into the pericardium were attached to the muscular structures, and two drainage-tubes were introduced. The patient was much collapsed after the operation, but responded readily to active stimulation. For a week the dressings were changed daily, considerable fibrinous pus being discharged. On the second day injections of iodoform-glycerin were made through the drainage-tubes, with excellent results. On the seventeenth day the tubes, which had been gradually shortened, were removed, and at the end of four weeks more the wound was firmly closed. Improvement in the general condition set in after the operation, and continued to ultimate recovery. Examination of the pus from the pericardium disclosed the presence of an organism resembling the bacterium coli communi in pure culture, but not capable of liquefying gelatin or of coagulating milk or of inducing the nitroso-indol reaction.

The third case is detailed by KIDD,[1] and occurred in a man thirty-four years old, who presented extreme dyspnea, both inspiratory and expiratory, with pallor of face, cold sweating, and anxious expression. The pulse-tension was high, and the left ventricle was hypertrophied and dilated. There was edema of the bases of the lungs, and a small pleural effusion on the right side. The urine contained a small quantity of albumin. Under treatment with morphin, trinitrin, and amyl nitrite improvement followed. After a time, however, the symptoms again became troublesome and paracentesis of the right pleura was performed, with the evacuation of three ounces of rose-colored fluid. Temporary improvement followed, but the symptoms again returned, and paracentesis had to be repeated, four ounces of fluid being on this occasion withdrawn. Several days after this operation, which afforded great relief, the patient complained of severe pain in the left side, and was much distressed. A double pericardial friction-sound was heard over the whole precordia. The application of six leeches to the cardiac region was followed by speedy relief. After the lapse of several days the patient was again suddenly seized with dyspnea and cardiac failure. It now became evident that the pericardial cavity contained a considerable effusion, and paracentesis was performed. Five ounces of blood-stained serum were removed, with great relief to the patient and improvement in the symptoms. The symptoms later again becoming alarming, paracentesis was repeated, twenty-eight ounces of fluid being removed. The patient was comparatively comfortable for two months, when his condition changed for the worse. Paracentesis was again attempted, but no fluid could be obtained. The patient gradually failed, and death finally took place. On post-mortem examination recent adhesions were found on both sides of the chest; the left pleura was adherent to the pericardium. The pericardial sac was entirely obliterated by adhesions, firm at the base, but very soft toward the apex and the lower part of the right ventricle. The pericardium was studded with numerous small hemorrhages, old and recent. The heart was greatly enlarged, the left ventricle being principally affected. The muscular tissue was rather soft. The cavity was moderately dilated. The valves were normal. The kidneys were much contracted. The capsules were thickened, but stripped easily, leaving a granular surface.

The results obtained in these cases ought to aid the judgment of the surgeon and strengthen his hand under conditions in which a policy of expectancy or non-interference is most likely, if not certain, to be attended with disastrous results.

ARTIFICIAL ANKYLOSIS FOR PARALYTIC DEFORMITIES.

There is no class of cripples so helpless, and for whom so little relief has been offered, as for those afflicted with deformities resulting from severe infantile paralysis. The quotation from *Timon, of Athens*, in Shakespeare: "'Tis not enough to help the feeble up, but to support him after," applies with greater force to this class of the deformed, as the instrumental relief afforded has to be maintained throughout life. In most afflictions the apparatus may be discarded at an earlier or more remote period, but not so in these paralytic cases; final dissolution alone separates apparatus from the afflicted, and the annoyance and expense connected with the purely mechanical treatment are readily to be appreciated. Any operative measure that offers a possibility of enabling such patients to dispense with mechanical appliances will be hailed with joy by the sufferers, and should be carefully considered by the profession until it has proved itself an aid to the sufferer, until it is to be regarded as entirely adequate, or, perchance, until it has advanced our surgical means to a more perfect method, of which this is but the inauguration.

The brilliant results achieved by operative measures in severe paralytic cases by De Forest Willard (Tenth International Congress, 1890, *Transactions of the American Orthopedic Association*, 1891) in the otherwise hopelessly deformed have stimulated others to a more careful study of the subject and a more earnest effort to assist these otherwise incurable cases. The labors of Gibney, Bradford, Young, McCurdy, and others have all demonstrated the importance of surgical measures in restoring to some degree of usefulness persons who would otherwise be doomed to spend their lives upon the floor or the bed.

In recent numbers of the *Provincial Medical Journal*, December, 1894, and January, 1895, Robert Jones, F.R.C.S.E., has proposed and has reported success in producing artificial ankylosis of the knee-joints and ankle-joints in paralytic flail joints. His purpose was to try to transform the flail limb into a member approximating as closely as possible to the splint which he wished to discard. The procedure consists in ankylosing the knee and partially ankylosing the ankle-joint. This has been performed in twenty-six cases, fifteen of which are published. The operation consists in opening the joint, and, with a scalpel or sharp gouge, peeling the superficial area of cartilage off the whole articulation in the case of the ankle, and gouging the bone in the case of the knee, keeping the joint completely at rest for some weeks subsequently, and for a long period fitting the limb with a simple apparatus which will enable the patient to walk without throwing a strain upon the newly fixed joints.

In operating upon the knee an incision is made across the front of the joint, covering fully half its circumference, and curved so as to pass the lower end of the patella. The flap is turned up and all the vessels ligated. The crucial ligaments are allowed to remain intact. Deep and superficial sutures are used to close the wound, no drainage-tube is employed, and an antiseptic dressing encloses the wound.

In the ankle-joint in old cases of paralytic equinovarus the joint is opened by an incision immediately in front of the external malleolus, following the line of the ankle-joint. Several grooved portions of the articulating cartilage are removed, including fragments of the articulating surfaces of the tibia and fibula. In some cases the astragalus is more easily reached from behind. The incision is made along the external border of the tendo Achillis.

No mishap attended the operation in any of the series; union has occurred by first intention, attended by little or no pain. Two separate splints are employed to fix the knee and ankle. After the operation it is necessary in all cases to prolong for a considerable period the use of apparatus, as it takes a considerable time for the joints to become so securely fixed as to bear the bodily weight and the ankle-lever strain.

The production of partial ankylosis in paralytic cases is a new suggestion, and, judging from the reports, an excellent one in selected cases. The number of cases in which such operation will be necessary will be comparatively small, especially in this country. Most American patients prefer apparatus to operation, and especially since the sudden changes of an unstable new country do not preclude the possibility of the poor of to-day becoming rich in the near future. The operation of artificial ankylosis is an operation for the poorer classes. In this class of cases excision of the knee-joint and ankle-joint has been seriously considered by AP MORGAN VANCE and others, and excision in order to secure a stiff joint, or arthrodesis, as it is styled by ALBERT, has been performed with excellent results by WINIWARTER, LESSER, J. WOLFF, RYDYGIER, and ALBERT. The operation of artificial ankylosis would, in those cases requiring such an operation, be the preferable procedure.

EDITORIAL COMMENTS.

The Homeopathic Department of the University of Michigan.—An interesting state of affairs exists at the University of Michigan. It appears that in 1875 the Legislature voted the establishment of a chair of homeopathic materia medica and therapeutics, and one of the practice of medicine, the students who listened to these professors attending also lectures on the remaining subjects by the regular professors, and being duly examined by these. As time went on the clinical professors in the Department of Medicine and Surgery objected to teaching "homeopathic" students, and additional "homeopathic" professors were added, to the number of five, the "homeopathic" students continuing to receive instruction in chemistry, physiology, bacteriology, hygiene, physiologic chemistry, physics, pathology, histology, etc., with the students of the Department of Medicine and Surgery. In time a hospital was built for the University, and subsequently also a homeopathic hospital. During the twenty years from 1875 to 1895 the homeopathic department has graduated 309 students at a net cost of $154,962, about $500 per capita. There are at present but seventeen students in the department, and of these twelve receive all of the instruction, with the exception of lectures in materia medica, from the regular faculty. The cost per student in the department of regular medicine equals $169. To reduce the double cost of two faculties, each with its own hospital, and the attendant loss, it has been suggested that the homeopathic school, as a department, be abolished, and that a professor of homeopathic materia medica and therapeutics be appointed. The dean of the homeopathic department proposes amalgamation. He would allow each "school" a professor of materia medica and one of the theory and practice of medicine, and would divide the operative chairs equally between them (thus surgery and obstetrics should go to one school, and gynecology and ophthalmology to the other); the rest of the chairs should be single, and some of the "useless" chairs should be abolished. We doubt if any such amalgamation is possible, although we see no objection to the incorporation of a course of lectures on homeopathy in the regular curriculum. There could be no better way of showing the good, if there be any, as well as the fallacies, the inadequacies, and the deficiencies of so-called homeopathic therapeutics. Such a plan is pursued in Germany, where homeopathy as an organized body does not exist. It is the privilege of the true physician to use any legitimate remedy or agency, whatever its source, that will relieve suffering or cure disease. The practice of the sectarian is limited to the applicability of his dogma.

Anti-Choleraic Inoculation in India.—There still appears to be some uncertainty as to the real utility of inoculations in the prophylaxis of cholera, although such evidence as is attainable rather supports the usefulness of the procedure. In the discussion of the subject at the recent Indian Medical Congress HAFFKINE (*British Medical Journal*, No. 1778, p. 219) related that the total number of persons thus treated in India is 32,166. Two-thirds of this number were subsequently inoculated with the second vaccine from five to twelve months after the first. During 1894, 3478 persons in Calcutta were inoculated. In thirteen houses containing 181 people cholera appeared from two to one-hundred-and-eighty days after the inoculation had been made. The number of persons inoculated in these houses was eighty-five, and among them one case which was fatal occurred, a percentage of 1.18. Among the ninety-six non-inoculated persons there were fifteen cases of cholera and eleven deaths, or 15.63 per cent. of cases and 11.63 per cent. of deaths respectively. In August, 1894, an epidemic of cholera broke out among 872 soldiers in Cawnpore. Seventy-five of these had been inoculated thirteen months previously. Among the whole number nineteen cases occurred, with thirteen deaths, all among the non-inoculated. In Lucknow there were among 640 non-inoculated persons 120 cases (18.75 per cent.), with seventy-nine deaths (12.34 per cent.), while among the 133 inoculated there were eighteen cases (13.53 per cent.), with thirteen deaths (9.77 per cent.). In no instance were the injections followed by unpleasant results. Observations were made of 2235 persons in Calcutta, Cawnpore, and Lucknow. Of this number, 500 were inoculated, and 1735 not. Among the former there were twenty-one cases of cholera (4.2 per cent.), with nineteen deaths (3.8 per cent.), while among the latter there were 174 cases (10.63 per cent.), with 113 deaths (6.51 per cent.). These results would appear to justify a continued use of the injections and to warrant the hope that we have really acquired a powerful means of mitigating the severity and reducing the mortality of one of the gravest plagues transmitted from antiquity.

The Treatment of Typhoid Fever—through the Newspapers.—Readers of THE MEDICAL NEWS may recall that in the numbers for March 3 and March 17, 1894, we took issue with the methods of Dr. J. E. Woodbridge in advocating, in a paper published in the *Journal of the American Medical Association*, the treatment of typhoid fever by means of whose nature no mention was at first made, but which was, however, given in a paper read four months after the first. Dr. Woodbridge's position was at the time defended and its own course justified by the *Journal*. One or more articles upon the same subject have appeared since our original comment, and quite a warm discussion has waged around the method of treatment. The last word on the subject comes from a lay journal, the *Youngstown Daily Vindicator*, which in its issue of February 4, 1895, devotes a large part of a column under the heading

"CAN BE CURED.
Interesting Paper Presented
By a Prominent
Physician,
Treatment of Typhoid Fever.
Dr. John E. Woodbridge gives
the results of his experience,"

to liberal quotations from "the current number of the *Journal of the American Medical Association*," from "a paper read by Dr. John E. Woodbridge, of this city, on the treatment of typhoid fever, containing reports of many cases of a serious character successfully treated. The paper was read by Dr. Woodbridge at the meeting of the Mississippi Valley Medical Association in Hot Springs."

Several formulæ and other details are given. We have no word of comment, but are deeply moved in admiration of the judgment and discrimination, not to speak of the local pride, of the home newspaper in thus spreading the fame of one of its distinguished fellow-citizens.

The Nostrum-Syndicates, the Law, and the Newspapers.—A bill is pending before the Tennessee Legislature to compel all makers of patent medicines to print the formulas of the remedies, against which the *Chattanooga News* thus protests:

> "We desire to enter here our most emphatic protest against this measure. It means a loss of hundreds of thousands of dollars to the State. No reputable manufacturer would think of giving away his formulas in this manner, so that anyone who chooses could take advantage of the legitimate secrets of his trade. Before they would divulge these secrets they would withdraw entirely from the State.
>
> "The result would be that the druggists, a large part of whose trade lies in patent medicines, would be deprived of a principal source of their income, the railroads would lose immense amounts of freight, and the newspapers would be almost ruined.
>
> "The advertisements of patent and proprietary medicines constitute a very large part of every newspaper's business, and many of the country weeklies would have to suspend publication if it were not for this patronage.
>
> "The day has passed when the best physicians refuse entirely to prescribe these remedies. Most of them find occasion at times to use them in their practice. The really skilful doctor is not injured.
>
> "The people are not imposed on to any large extent. They soon discover what is fraudulent and what is of genuine merit. The bill can help no one but physicians who have not the ability to command practice on their own merits, but who hope by this means to compel patients to call on them."

It is not often that a bribed editor is thus honest and frank. We reproduce the "argument" to illustrate the difficulties that hamper medical progress in our country and that throttle legislation and reform of the outrageous abuses which both the profession and the people endure.

The "Special Edition" with Portrait and "Write-up."—Such, we believe, is the newspaper jargon for expressing a method of uniting journalistic and professional "enterprise." According to an illustration before us as we write, the price of a "write-up" of fifty lines, with "scetch" (sic) and portrait of the doctor, in "the quarter-century anniversary edition of the Indianapolis *News*" is $35.00. We have received during the past year a large number of newspapers from all over the land, containing numerous "scetches" and "write-ups" of all the local physicians, sandwiched between the ditto ditto (as Artemus Ward would say) of the no less enterprising butcher, baker, and candle-stick maker. We suppose that with the advertisements of *cancer-cures* and *Wizard Kings of Pain*, and *Lost Manhood Restored*, these respectable, most respectable, members of the American Medical and many other Associations thus naturally contribute to the support of journalistic and medical ethics. No wonder at the professional opposition to the Code of Ethics! The "write-up," as if out of the kindness of heart, and from local patriotism of the newspaper editor, that is to say, the reading-notice in the editorial columns, costs more than a plain, straightforward "ad." in the other columns. Now the Code of Ethics compels the "hustler" to pay the higher price for the reading-notice. No more effective ground for hatred to the Code could be imagined, and we therefore suppose we shall have a subacute attack of codephobia of especial virulence in Baltimore next May.

Argon is the name finally given the new element or gas discovered in the atmosphere by Lord Rayleigh and Prof. Ramsey. The word is derived from *ἀγ* priv., and *ἔργον* work, and is thus allied to the old medical words *anergia* and *anergic*, and is given to the substance because of its remarkable inertness. Argon is soluble in water to the extent of four in one-hundred volumes. Its density is 20, its atomic and molecular weight 40. It condenses to a colorless liquid at —128.6° C., and under a pressure of 38 atmospheres and at a lower temperature it freezes to a crystalline mass resembling ice. Its freezing point is —189.6° C., its boiling point —187°. Professor Crookes concludes that perhaps two new elements are contained in the substance, as it yields two distinct spectra. There are many physiologic and medical questions suggested by its presence even in such small proportions as 1 : 125 or 1 : 200 in our atmosphere, but so far these exist only as queries half-formed and wholly unsolved.

Medicine or Manslaughter?—The lay-public is justly exercised over the report, purporting to come through the engineer (an English officer) upon the Chinese vessel the *Yang Wai*, that after an engagement with a Japanese man-of-war the hopelessly wounded were at once put to death by the surgeons in charge, by means of prussic acid. Were the surgeons Englishmen or Americans, and is the report true? Can any one send us reliable information?

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF GREIFSWALD.

Meeting held November 3, 1894.

NOTE.—The account of this meeting is published at this late day as the discussion seems to emphasize in a greater degree than has been done elsewhere the importance and the necessity of joining systematic local measures with the specific treatment.

MOSLER reported that from October 1, 1893, to October 1, 1894, 351 cases of diphtheria had been treated at the clinic at Greifswald (287 children and 64 adults). Among these there had been only 40 deaths (39 children and 1 adult). At the medical clinic held at the University Hospital 313 were treated, with 46 deaths (15.5 per cent.). Of these last a number were sent to the hospital on account of the severity of the disease, and among them many arrived moribund. It was not until August, 1894, and when the epidemic was disappearing, that Behring's treatment was employed. Thirty cases were treated by this method, with remarkably good results.

It was said that expectations for the serum-therapy must not be too much exaggerated. It is not a panacea for all cases of diphtheria. Its action is uncertain in those cases in which the diphtheria-germs are associated with other pathogenic microörganisms, such as the streptococcus. However, in these mixed cases the suppression of the effects of the diphtheria-poison will perhaps have a good effect. It remains for the physician to determine what remedies shall be used in connection with the serum-therapy in these cases of mixed infection.

BÖRGER reported 30 submitted to the serum-therapy, of which only two had died. Five had tracheotomy performed, and of these one had died. The reports for the same months of the preceding year, however, gave equally good results, the average mortality being 15.5 per cent., and this, of course, was previous to the introduction of the serum-therapy. It shows the skill with which cases of diphtheria were treated in this clinic.

LOEFFLER stated that the bacillus of diphtheria does not usually penetrate the organism. Since it only develops locally and produces its poison, it would seem to be advantageous to destroy the colonies where they exist. The local treatment of diphtheria is, therefore, logical.

In cases of sore-throat caused by other pathogenic microörganisms than the diphtheria-bacillus the serum has no effect. In cases in which the diphtheria-bacillus is associated with other microörganisms local treatment is equally indicated. Then, too, the local treatment has the advantage of preventing the spread of the pathogenic agents.

LOEFFLER said he had found a large number of antiseptics capable of destroying cultures of the diphtheria-bacillus in twenty seconds, but in most cases it is not possible to submit the patient to the action of these remedies during so long a period. He had, therefore, attempted to find an agent of still more rapid action. After many trials he had found that a mixture of 60 parts of alcohol, 36 of toluol, and 4 of solution of ferric chlorid destroyed these cultures in five seconds. Experiments made on animals with this mixture yielded excellent results. During the last epidemic many physicians had applied this remedy, and among 70 cases not a single death resulted. At the clinic of Mosler 36 cases were treated, with 5 deaths, but these cases were too far advanced to be benefitted by local treatment.

When the treatment is properly applied in cases of diphtheria in the first twenty-four hours the temperature falls one or two degrees, the pulse becomes slower, and the general condition is improved as much as when serum-therapy is employed. When the treatment is begun early paralysis never follows.

When the remedy is energetically applied it causes a burning pain. To prevent this, Strübing has advised the addition of menthol. The following mixture is less painful:

Menthol	10 parts.
Toluol	36 "
Alcohol	60 "
Ferric chlorid	4 "

Hydrogen sulphid is produced in the pharynx in putrefactive processes, and this precipitates the ferric chlorid in the form of iron sulphid, lessening the effect of the mixture. In these cases it is best to substitute two or three c.c. of creolin or metacresol for the ferric chlorid. These mixtures have a very energetic action on all other pathogenic microörganisms, as well as on the diphtheria-bacillus. All sore-throats may be treated by them with good results.

STRÜBING said that in one epidemic one-fourth of the cases were not true diphtheria, but pseudo-membranous sore-throat, produced by other organisms, and particularly by the streptococcus. It is very interesting to note that under the same conditions in which true diphtheria develops we find also an extraordinary number of "diphtheroid" sore-throats due to other microörganisms. These cases, usually of a very benign character, are sometimes exceedingly malignant. If the microörganisms present penetrate into the tissues and bloodvessels the streptococcus multiplies there, and the patient succumbs similarly to cases of streptococcous septicemia. In certain conditions these "diphtheroid" sore-throats become putrid, as in true diphtheria. The submucous tissues become infected and cause phlegmons of the neck. Unfortunately serum-therapy is powerless against the streptococcus, and the physician must resort to local treatment.

If a case of diphtheria is seen on the first or second day, it is not necessary to employ the anti-diphtheric serum, for the "Loeffler mixture" is sufficient to check the course of the disease. If the disease is more advanced, the serum should be employed, but even the serum may be powerless in the presence of a mixed infection; so the local treatment should also be employed. The "Loeffler mixture" is the most efficient local application of any that have been used up to the present time. As its use, however, is attended with pain, so soon as the disease is controlled and the temperature returns to normal, it is better to substitute other remedies, especially mercuric chlorid. It must not be thought that the "Loeffler mixture" is free from objections. Its use is always attended with more or less pain, and, if applied too strong, it injures the mucous membrane.

It is impossible to give a general formula for repeated local treatment in all cases. One must be guided by the extent and duration of the disease. If the case is a very severe one, the mixture should be applied on cotton tampons, eight or ten applications being made at one sitting, and the sittings repeated every three or four hours till the fever disappears.

A serious obstacle to the local treatment is the extension of the lesions to the nasal passages or the respiratory passages. The applications cannot then be employed, or, if they could, the mucous membrane of the larynx and nose will not tolerate this powerful remedy.

Fenderich reported 191 cases of diphtheria treated at the surgical clinic at the University from April 1, 1887, to April 1, 1894. This was, of course, before the introduction of serum-therapy. Of the total number 114 (57 per cent.) died; in 153 cases (77 per cent.) tracheotomy was performed, and 100 of these died. In the last year alone tracheotomy had been performed in 96 cases, of which 25 had recovered.

Beumer reported that in one house in which there were five cases of diphtheria, two being fatal, he had treated the sixth child with serum, and it was not affected with diphtheria. Some days later, in an asylum containing 17 children, 3 having contracted diphtheria, the others were vaccinated with serum; and, in spite of the bad sanitary conditions present, none of them developed diphtheria.

As to the production of albuminuria after the injection of the serum, Loeffler states that the excretion of toxins by the kidneys causes a lesion of these organs, which does not manifest itself at once, because the kidneys can bear a certain amount of the poison.

Peiper stated that in a case of true diphtheria treated by injections of serum, albumin did not appear until the end of two weeks, and lasted only four or five days. No casts were found in the urine. Three weeks after the injection the child had an ocular paralysis.

Loeffler said that side by side with the true diphtheria-bacillus which is found in the mouths of patients recovering from diphtheria, the pseudo-diphtheria-bacillus is also found. The latter has little pathologic importance except that it is an attenuated form of the true bacillus. We do not know if the true form which has lost its virulence can be made to regain it. However, in individuals in perfect health the virulent form has been found, and in this way the disease may be disseminated. These virulent bacilli are found in the mouths of persons who have had diphtheria for a variable time after recovery. For this reason the German committee proposed at the Congress at Budapest not to allow children that have had diphtheria to return to school until bacteriologic examinations of their mouths no longer disclosed the presence of diphtheria-bacilli.

Abel reported a series of researches on the immunizing power of the blood-serum of persons recovered from diphtheria. This power has only been proved to exist for six or seven days after recovery. On the other hand, it has been found to exist in some cases for eight or ten days, and in a few cases for some months. This shows that a first attack of the disease does not absolutely prevent a second.

The blood of persons who, according to their statement, have never had diphtheria has also been examined. In most cases it had the power to protect guinea-pigs against diphtheric infection.

Wasserman has already shown that this property of human serum becomes more pronounced with the progress of age.—*Le Bulletin Médical*, December 2, 1894.

CORRESPONDENCE.

SYMPHYSIOTOMY.

A Personal Protest by Dr. Henry J. Garrigues, of New York.

To the Editor of The Medical News,

Sir: In the number of The Medical News issued on January 12th Dr. W. Winterberg, of San Francisco, Cal., in an article on symphysiotomy, writes: "The upper limit is placed at 88 mm. by the majority of operators, while Dr. Garrigues advocates 95 mm. in a flat, and 11 cm. in a generally contracted pelvis, on the ground that the latter offers the same resistance as a flat pelvis with a conjugate 13.5 mm. (0.5 inch) shorter.

"This proposition of Dr. Garrigues is unintelligible. It certainly is paradoxical to talk of a generally contracted pelvis with a conjugata vera of 11 c.m. The normal length of the true conjugate is 11 c.m., therefore, with one diameter perfectly normal, a *general* contraction cannot be said to exist in such a pelvis."

Before designating my sayings as *unintelligible* and *paradoxical*, Dr. Winterberg should have ascertained what I said. Three times I have addressed the profession on the subject of symphysiotomy, namely, in the *American Journal of the Medical Sciences*, March and April, 1893; the *American Journal of Obstetrics*, November, 1893; and the *Medical Record*, November 10, 1894. In all these publications I place the upper limit for symphysiotomy at 3½ inches, 9 cm., in the flat pelvis, and at 4 inches, 10 cm., in the generally contracted.

I do not know with what right Dr. Winterberg adds 5 mm. to the first measure and 10 to the last.

Morisani places the upper limit at 88 mm.; 3½ inches are 89 mm.; and since nobody can measure either 1 or 2 mm. in a pelvic diameter of a living person, there is practically no difference between the upper limits in the flat pelvis as stated by me and the majority of operators, and it is better to have round, approximately correct figures, such as 3½ inches and 9 c.m.

As to the normal antero-posterior diameter of the superior strait, it is 11, or, according to some authorities, even 11.5 cm. One of 10 cm. is, therefore, abnormally short, and when at the same time the transverse diameter is too short the pelvis is generally contracted. Just as it is a rule, followed by the best obstetricians in regard to the lower limit for the application of the obstetric forceps, to demand one centimeter more in the length of the antero-posterior diameter of the brim of the *generally* contracted pelvis than of the flat pelvis, I think it proper to make a similar addition to the true conjugate in placing the upper limit for symphysiotomy.

This is of particular importance to us here in New York—and according to Dr. Edward Reynolds (*Transactions American Gynecological Society*, 1892, xvii, p. 124), the same applies to Boston—as the form of narrow pelvis we have to deal with nearly always is the generally contracted pelvis and not the flat, which is the common form in Europe.

To this must be added that the average weight of American children is ⅓ pound heavier than that of French children, more than ⅔ pound heavier than that of German children, and even 1⅙ pounds heavier than that of English children, taking Lusk, Tarnier, Spiegelberg, and Playfair as representative authors for their respective countries.

There seems, therefore, to be good reason for American obstetricians to place the upper limit for symphysiotomy somewhat higher than they do in Europe.

There are other points in Dr. Winterberg's article to which I would take exception, but as I have no inclination to begin a controversy—and this would draw the attention away from the main point—I shall limit myself to this protest against being misquoted and then told my teaching is unintelligible and paradoxical.

Respectfully,
HENRY J. GARRIGUES.

Medical Coeducation in Paris.—The medical faculty of the University of Paris opened its doors to women in 1868, but at first only a very few availed themselves of the privileges thus offered. In 1878 the number in attendance was 32; during the next ten years (1878–'88) it increased to 114, and is at present 183, of whom the great majority (167) are Russians. The remainder are Poles, Roumanians, Servians, Greeks, and Scotch, and only one German. Many of them, chiefly Russian, have been through the gymnasium; others have acquired a more or less thorough knowledge of literature, history, the natural sciences, and philology in such secondary schools as were accessible to them. As foreigners, they must all be examined in Latin and Greek before admission, and be able to translate passages from the easier classical writers, Cæsar and Xenophon, at sight, and to analyze them grammatically. The courses of study are pursued conjointly with the young men, and this association, so far from producing a demoralizing effect, tends to elevate and refine both sexes. One lady declares that during an experience of three years in the clinique, the auditory, and the dissecting-room she has never observed that the presence of young ladies occasioned the slightest improper word or act on the part of their male colleagues. Most of the women who practise medicine in Paris are married. "Model wives and happy mothers, they nevertheless find time to devote to their profession." The professors and directors of the hospitals praise the conscientiousness and diligence of the women, and acknowledge them to be, both in general intelligence and in special knowledge, fully equal to the men. The latter also admit the truth of this statement, and assert that they ought to be even superior in these respects, since they are not compelled to waste their time in cafés and cabarets. It is still difficult for some of the older members of the faculty to reconcile themselves to the new state of things.—*New York Evening Post.*

Meetings of Philadelphia Medical Societies:

	Meets.	Next meeting.
Academy of Surgery,	1st Monday of month, Oct.—June.	March 4
College of Physicians,	1st Wednesday of month, Sept.—June.	March 6

ORIGINAL ARTICLES.

SURGICAL TUBERCULOSIS.[1]

BY NATHAN JACOBSON, M.D.,
OF SYRACUSE, N. Y.,
PROFESSOR OF CLINICAL SURGERY, COLLEGE OF MEDICINE, SYRACUSE, N. Y.; SURGEON TO ST. JOSEPH'S HOSPITAL, SYRACUSE, N. Y.

SURGICAL tuberculosis, I take it, includes such forms of tuberculous disease as may be amenable to surgical treatment. Each year, as these pathologic conditions are better appreciated, the possibilities of surgical help increase.

Tuberculosis appears in various guises: Lupus is skin-tuberculosis; the connective tissue has its tuberculous abscesses; in the nose, mouth, and larynx it is seen as a primary affection, to say nothing of the lungs, where it is most frequently encountered. Tracing its course further along the mucous membranes, we find it invading the alimentary canal, appearing in the genito-urinary tract of both male and female, and awakening peritoneal infection. Again it is seen in the glandular structures, most frequently in the neck. The long and short bones, the joints, the spine are common sites of its occurrence. The special organs are not free. In fact, it would be difficult to suggest a structure in which it has not appeared as a primary disturbance. Diseases formerly called by other names are now recognized as being tuberculous, under which head we might mention scrofula, caries, tumor albus, and hip-joint disease. Even the deeply placed organs, as the kidneys, the Fallopian tubes, and ovaries, do not escape the incursions of the tubercle-bacillus. This enumeration, in itself very incomplete, suggests how inexhaustible must be the subject of the surgical treatment of tuberculosis. I can, therefore, present the disease in but a few phases, and, rather than attempt to consider its many different surgical forms, shall restrict myself to the discussion of the more frequently encountered varieties.

A brief preliminary word before we enter upon our specific task. No one to-day holds to the constitutional origin of tuberculosis. We must regard it as a local infectious disease, awakened by the introduction of the specific germ into tissues whose resistance has been lowered. That tubercle-bacilli can enter through unbroken mucous membranes is not to be questioned. Cornet presented the result of his experiments to the French Surgical Congress in 1889, in which he showed that tuberculous glandular swellings could be produced in guinea-pigs as the result of rubbing tubercle-bacilli into a mucous membrane without lacerating it. At the request of Volkmann, Schuchardt studied so-called scrofulous invasion of the skin and mucosæ presenting nothing unusual microscopically. In an instance of eczema of the forearm the bacilli were found between the scales of the epidermis. These points suggest the manner in which the local forms of tuberculosis originate.

However introduced, whether finding its way to glands through the mucous membrane, by way of the lymphatics, or discharged into the blood-current and locating itself as an embolic plug at a remote part of the body, the infection establishes itself first locally, heaping up its characteristic nodules, involving the surrounding structures, building up large fungous growths or forming caseous masses, ultimately producing local abscesses, or leading to constitutional disturbances. Again, it may awaken in the surrounding tissues reactionary inflammation, and secure thus a spontaneous arrest of the tuberculous process, while the bacilli and their spores, possessing remarkable vitality, may lapse as it were for a time in a state of "innocuous desuetude." Baumgarten discovered in autopsies made upon persons dying of other than tuberculous diseases, that one out of every four had latent tuberculous foci in the lungs. And so elsewhere in the body, the tuberculous areas may become quiescent, and particularly so under conditions favorable to such a result. Thus a tuberculous affection of the lungs or other structures need not necessarily lead in the first instance to death of the individual, nor in the latter to local necrosis.

GLANDULAR TUBERCULOSIS. Not all chronic enlarged glands of the neck are tuberculous. Much the larger percentage, however, of those that show no disposition to diminish, but remain latent or increase in size, and especially if they exhibit a tendency to suppurate, are tuberculous. The general physician has been accustomed to treat this latter condition with poultices. When the glands have broken down and pus has reached the surface he makes an incision and gives vent to the purulent collection. Nature has to do the rest. No more unsurgical course could be pursued.

---

[1] Read before the Onondaga County Medical Society, December 18, 1894, being part of the discussion on "Tuberculosis."

The tuberculous character of the glands being recognized, two lines of treatment are open: First, to secure the removal of the glands before the surrounding structures are involved; or, second, to wait until the structures are broken down, when we have to deal not only with glandular but also with periglandular inflammatory disease.

At the meeting of the British Medical Association, in 1893, it was the consensus of opinion of the section discussing this subject, that medical treatment in itself is of no avail beyond the benefits that come from improving the general tone. The early removal of the glands is advised, first, for esthetic purposes, as late removal of these structures leads to unsightly scars. But their removal for pathologic reasons is more to the point. If the glands can be excised without infecting the surrounding tissues, the wound can be closed, and union by first intention results. If a single gland is found caseous, the other glandular enlargements are probably in a similar condition, and their removal is desirable. Care should be taken to excise the glands entirely, as any tuberculous focus left behind will generate suppurative inflammation. The incision should be free enough to give access to all diseased masses. Some surgeons make a series of small incisions over the individual glands in order to avoid any apparent disfiguration. Others seek to establish a line of incision at a point where the scar will be least visible.

It is particularly to suppurative cases that I desire to call attention. To incise simply the abscess is not to lay bare the tuberculous focus. The diseased gland may simply be connected with it through a sinus. Again, one leaves behind the broken-down tuberculous mass a collection of infectious material. These cases demand free incision, thorough curetment with a Volkmann spoon, disinfection with a sublimate-solution, and packing with iodoform-gauze. The danger of disseminating tuberculous disease by these steps is very small indeed. The operation for the excision of tuberculous glands, whether caseous or suppurative is a perfectly innocent procedure.

There is another phase in which these conditions should be regarded, that is, the danger, if allowed to remain, of remote infection by them. It is a common observation to see individuals with tuberculous glands develop at a later period pulmonary or other forms of tuberculosis. A child that was seen by me two years ago, with tuberculous lymphatics of the neck, and whose mother would not consent to their removal, this summer suffered from an extensive tuberculous iliac abscess.

BONE-TUBERCULOSIS AND JOINT-TUBERCULOSIS. With the ever-increasing fund of knowledge, new principles in tuberculous disease of the bones and joints are being constantly established. It is therefore proper to refer again to this subject. Tuberculosis has a predilection for bones or portions of bones largely made up of cancellous tissue. So we have tuberculosis of the vertebræ or "Pott's disease," manifesting itself as a most frequent form of bone-disease. Of the joints, because of the histologic structure of their bony constituents, the knee and the hip are most frequently affected. In four-fifths of the cases other tuberculous manifestations co-exist.

To diagnosticate the condition before the destructive stage of tuberculosis is reached is most essential. There is every reason to believe that we can arrest the lesions in their early stage. Allowed to suppurate, impaired function and deformity are the best result that can be attained. Chronic joint-inflammation requires surgical rather than medical treatment. Fixed points of tenderness, nocturnal pain, muscular rigidity, and particularly muscular atrophy, impaired function, changed position and form, are to be carefully noted.

Not only does timely treatment secure more serviceable extremities, but with their neglect tuberculous diseases of bones and joints may awaken remote infection. A case that I saw with Dr. Murray and reported by him, in which pulmonary tuberculosis followed upon tuberculous disease of the wrist-joint, exemplifies this. The close relationship between pulmonary tuberculosis and joint-tuberculosis is likewise evident in the subsidence of serious tuberculous lesions in the lungs upon removing a tuberculous joint. As an example of this kind I have to refer to a case seen by me in April, 1886. A tuberculous hip received conservative treatment, and the disease became quiescent. Subsequent traumatism reawakened the trouble; with the recurrence came hectic fever, night-sweats, emaciation, pulmonary invasion, and pulmonary hemorrhage. On the 27th of April, 1887, I resected the hip. Despite the boy's reduced condition, he made a recovery, not only as to the condition of his extremity, but the pulmonary disease became retrogressive, disappeared, and he has remained well since, now seven years.

When the infectious character of bone-tuberculosis became recognized surgeons at once took the ground that the only course to be pursued was the removal of the tuberculous site. This led to an enormous number of minor operations and resections upon the bones and joints in search of the diseased area.

In the early period of tuberculous invasion of joints of the lower extremities nothing has accomplished so much as rest in the recumbent posture, with weight-extension. The period of time to be occupied by this treatment is much longer than is usually deemed necessary. Failure to observe this leads to failure of the treatment. Howard Marsh, one of the most earnest advocates of this line of procedure, states that the average period required for the cure of these cases is about eighteen months. He makes it a rule never to allow a patient to be up until at least three months have passed after the cessation of pain. He has found that the maintenance of the horizontal position for one or two years, in good air, with weight-extension, is not prejudicial to the patient's health. Only once I have found it necessary to continue the confinement in bed over one year. This boy improved in health steadily during the entire period.

When the disease has led to marked organic disturbance, further steps become necessary. During the so-called antiseptic period, and until within a very recent period, operative intervention has been the accepted method for treatment. Under it, Schede and others, in the advanced cases, however, had a mortality of 66 per cent.

Tuberculin, when introduced, was claimed to be a panacea for all tuberculous affections. It was tried in cases of surgical tuberculosis. Much was expected, and its use became general, but in spite of the glowing accounts of its excellent qualities the mortality steadily increased until 75 per cent. of those treated with it who were suffering from tuberculous joint-disease died. On the other hand, a line of procedure has now been instituted which has had most marvellous effects. It is the introduction into the joint of a sterilized solution of iodoform in glycerin or oil; 10 or 20 per cent. solutions are injected. Of the former, ten c.c., that is, two-and-three-quarters drams, and of the latter one-half that quantity is used. At the end of eight days a second injection is made. In the meantime cold applications are applied to the joint. Depending upon the severity of the case, the number of injections varies. Absolute contact with the diseased surface is necessary. Some discontinue its use, if no benefit follows four or five injections. This treatment has been pursued quite extensively in this country, and I have had not a little experience with it. The mortality has fallen to 20 per cent. under the iodoform-emulsion, and the number of resections has been reduced one-half. Upon this point the German surgeons are substantially agreed. Bergmann, for example, prior to 1891, resected from thirty to forty hip-joints annually. During that year, with the same number of cases presenting themselves, he operated upon eleven. Of thirty-six tuberculous knee-joints, thirty-one were cured by injection, and only five had to be operated on. The fixed policy of the German surgeons to-day is not to resort to operative intervention until conservative measures have been given a fair trial.

In France Lannelongue has been using a 10 per cent. solution of zinc chlorid. Instead of injecting it into the joint, he applies it just outside of the diseased area, for the purpose of lighting up there, as Nature herself often does, a reactionary inflammation. He introduces a hypodermic needle into different points about the joint, as close to the attachment of the capsule to the bone as possible, until he has gone completely around it. Before the application the joint is placed in its normal position. The operation is done under antiseptic precautions, with the patient anesthetized. It is not repeated in less than three weeks. Other solutions have been used. One deserving mention is the suggestion of Landerer. In 1892 he began the use of a solution of cinnamic acid, five parts to ten of olive-oil, the yolk of one egg, and 100 parts of a normal saline solution, rendered alkaline before its injection. Of all, however, the iodoform-emulsion alone has established itself securely with the profession.

As to the ultimate course of joint-tuberculosis, one of the most interesting studies presented recently is the report of Bruns to the German Surgical Congress, last April. With Dr. Wagner he carefully reviewed the records of the surgical clinic at Tübingen for the past forty years. Six-hundred cases of hip-joint disease had been treated during this period. Of these, upward of two-hundred are yet alive, and each was personally examined. That no doubtful case might be considered as tuberculous, all that ran a course of less than a year-and-a-half, or such as recovered without impaired function of the joint, were excluded. In this way the number was reduced to 390; 321 had been treated conservatively, and 69 by resection.

Tuberculous coxitis was found to be a disease appearing substantially during the first two decennial periods of life, 85 per cent. of the cases having occurred before the twentieth year. In one-third there had been no suppuration; in the other two-thirds abscesses and sinuses existed; 55 per cent. recovered under conservative treatment, the average period being four years; 40 per cent. died of tuberculous diseases of the internal organs. The appearance of suppuration increased the mortality 23½ per cent. The earlier in life the disease appeared the more favorable was found to be its course. Thus, 65 per cent. of those existing during the first decennium recovered; in the second 56 per cent.; in the third and fourth 28 per cent., while no recoveries occurred in cases appearing after the fiftieth year. A number recovering from the tuberculous disease of the hip-joint succumbed later to other forms of tuberculosis. Those who as children had been severely sick, had been puny and wretched, after a period of from ten to thirty years were found to be perfectly healthy, vigorous, and, though deformed, did not deserve the name of "cripples." Joint-motion was restricted in all; in one-third it was partial; in two-thirds there was almost complete ankylosis. Faulty position existed, usually flexion with abduction, compensated to a certain extent by the pelvis. There was shortening, varying from one to twelve centimeters. Only a German surgeon would so thoroughly follow up a list of cases covering a period of nearly half a century and determine their ultimate outcome.

PERITONEAL TUBERCULOSIS. Permit me to glance hastily at another form of tuberculosis which, during recent years, has become amenable to surgical treatment. I refer to the peritoneal variety. Like forms of tuberculosis attacking other serous cavities, as the pleural or synovial, it is usually dependent upon a neighboring tuberculous focus. It may be associated with the genital tract in woman. Recently it has been discovered that conditions which had presumably been considered purely inflammatory, involving the ovaries and Fallopian tubes, are frequently tuberculous. Tuberculous peritonitis is not by any means restricted to adult life. Hartman, in 1892, collected, almost entirely from French literature, forty-eight cases in which children had been operated upon for tuberculous peritonitis, and only two of whom had died. The disease appears under different forms. First as ascites, in which the fluid is either clear or turbid or occasionally purulent. Here the serous membrane is found studded with miliary tubercles. A second variety presents thick adhesions, walling off this fluid into well-defined cavities and conveying the impression to the clinician of the existence of a localized cystic tumor. In the third group the tissues are matted together, the intestines glued to one another, even to the degree of intestinal obstruction, ulcerated or perforated. The lymphatics are enlarged and caseous at times, but no fluid is present. Pressure may lead to extensive edema of the lower extremities. Such was the condition in a case that I have reported, in which the primary focus was located in a midlumbar vertebra, the retro-peritoneal glands being greatly enlarged and in which there co-existed tuberculous disease of the kidneys and bladder.

Medicinal treatment has proved of but little benefit, although cases have recovered without operation, in which the diagnosis of tuberculous peritonitis has been made. One such case I have seen. Henoch, however, laid down the rule that all cases of chronic peritonitis that recover spontaneously are not tuberculous. As opposed to the medicinal treatment in these cases, the benefits that have almost universally attended celiotomy have been one of the surgical surprises of recent times. How opening the abdominal cavity benefits this condition no one knows. The explanations offered are altogether too numerous to review. The profession is agreed only so far that celiotomy does cure. It seems to be more beneficial in the ascitic cases, whether the fluid be in the free peritoneal cavity or restricted by adhesions. It is of much less benefit in the third group, in which there is no fluid, but in which marked plastic disturbance exists.

The number of cases operated upon is very large. Unless there be general tuberculosis, the operation is not contraindicated. Talleyrand has said statistics are but lying figures, yet probably the result is fairly stated by Koenig, who, in 1891, had collected one-hundred-and-thirty cases, with a death-rate of 3 per cent., and with a record of twenty-three improved and eighty-four cured. Almost the earliest recorded case is that of Spencer Wells, operated in 1862. The patient, an unmarried lady, presented an abdomen distended to the size of a full-term pregnancy. A cyst was suspected, but instead there was ascites, and the peritoneum was found studded with myriads of tubercles. The woman recovered, and now after more than thirty years remains free from any subsequent disturbance. A young lady upon whom I operated upward of four years ago remains perfectly well.

GENITO-URINARY TUBERCULOSIS. The genito-urinary tract is found to be frequently the seat of primary tuberculosis. From the meatus to the supra-renal capsule no tissue seems to have escaped primary invasion, while in both sexes the genital tract, at various points, has likewise been the initial site of tuberculous disease. Occurring in the urinary organs it is not always possible to establish a diagnosis, as the tubercle-bacillus is not readily found until the disease has advanced perhaps beyond operative relief. Schuchardt has remarked that tuberculous invasion is more frequently of venereal than of hematogenous origin. A mixed infection may exist when apparently only the characteristic sore of primary syphilis is present. Later the glands show that there has been tuberculous invasion. With gonorrhea, tuberculous epididymitis has occurred, although the first appearance differs in no regard from ordinary gonorrhea, except that tubercle-bacilli are found associated with the gonococci. The introduction of tubercle-bacilli without laceration of the mucous membrane occurs, he claims, after the manner mentioned earlier in this paper. But, however, entering, the tubercle-bacilli have found in the genito-urinary organs sites most favorable for their development, and when awakened we have to deal with one of the most unfavorable forms of tuberculosis from a prognostic standpoint. When the primary manifestation is in the epididymis, or testicle, the only safeguard against further invasion is the removal of the tuberculous focus, which at least is possible in this situation.

An interesting case of this kind has been under my observation for fully ten years, in which the patient, a clergyman, has suffered from tuberculous disease of the epididymis, prostate, and bladder, and later of the sternum. Under conservative treatment he has been able to continue with his pastoral duties, and is indeed quite vigorous. On November 10, 1893, a patient who had presumably been suffering from an ordinary attack of gonorrhea since the preceding spring presented himself to me with a fistulous opening on the right side of the perineum. Flabby granulations existed at the opening, and the surrounding structures were infiltrated. His attending physician had diagnosticated an ischio-rectal abscess. However the injection of hydrogen dioxid into the sinus found its way out of the urethra at the meatus. A close observation of the case led to the conclusion that it was associated with deep-seated urethral tuberculosis. The wall of what had been a cold abscess and its fistula were curetted clear up to its prostatic commencement, and perineal section was peformed. The bladder was drained by a catheter carried through the perineal orifice for a month, during which period granulations sprang up, and the urethra was walled off from the old abscess-cavity. Slow convalescence followed, and in the course of six months the parts became thoroughly healed and remain so.

When the tuberculous site is higher up, that is to say, either in the bladder or kidney, the outlook is particularly unpromising. Removal of a tuberculous kidney, justifiable only when the disease is limited to one, is, as has been my experience, followed often by death from pulmonary tuberculosis. Nor is it always possible to determine where the primary focus is located. An example of this was found in a patient upon whom I operated at St. Joseph's Hospital, February 18, 1893, for an enormous iliac abscess of the left side. Both anterior and posterior openings were made and several quarts of pus evacuated. A coincident cystitis led me to believe that we were dealing with tuberculous disease of the urinary tract. The opinion was expressed that the kidney was probably the primary source of the infection. Our bacteriologist failed to discover tubercle-bacilli. Later on it became necessary to open through the acetabulum to secure better drainage. The patient improved sufficiently to return to his home. After a brief respite the disease again rapidly advanced, and the man died. Dr. Breese, who had attended him during his sickness, was permitted to make an autopsy, and informed me that a fistulous tract crossed the body to the right kidney, which was disorganized by disease, while the left, upon the side corresponding to the abscess, was not involved.

This many-sided disease could occupy one indefinitely in merely superficially examining its various phases. I had expected to consider other forms in which the surgeon frequently encounters tuberculosis, but I have already occupied too much time.

ANTE-PARTUM OPHTHALMIA NEONATORUM. (INTRA-UTERINE OPHTHALMIA

BY HARRY FRIEDENWALD, M.D.,
OF BALTIMORE.

A NUMBER of States have passed laws with a view to decrease the still large proportion of blindness due to ophthalmia neonatorum. Among these States we are happy to name Maryland, whose last Legislature showed its wisdom in enacting a law making it a punishable offence for a midwife or other person having charge of an infant to treat any ophthalmia, and necessitating the calling of a physician. These laws are the outcome of the experience that ophthalmia neonatorum is a very tractable disease when properly cared for. Some physicians have gone so far as to claim that this disease is always curable when treated early. But even our best ophthalmic surgeons occasionally lose a case through corneal involvement, and recent discussion proves that it is an unavoidable accident in an *exceedingly small number* of cases.[1]

It is important to examine into the various conditions under which cases are lost and to determine how they lead to blindness in spite of prophylactic measures and of early and proper treatment.

Ophthalmia neonatorum develops, as a rule, on the second or third day after birth. Infection usually occurs during the passage of the child's head through the vagina. The intervening time is known as the period of incubation, during which the eye presents no signs whatever of disease. This period lasts at least twenty-four hours. It so rarely happens that the disease makes its appearance earlier than the second or third day that none of our text-books makes mention of it. And yet there are a number of cases on record of children born with the well-marked signs of this disease. In these cases the period of incubation had passed, and the stage of inflammation was more or less advanced at birth.

The entire number of such cases that I have been able to collect in medical literature is eighteen. They are as follows:

1. Hirschberg[2] saw a child, twelve hours old, with well-marked ophthalmia neonatorum; there was swelling of the lids, pus in the conjunctival folds, and a diffuse opacity of both corneæ. Labor had been easy, but the membranes had ruptured three days before. The final result was a small

---

[1] Randall: Trans. Amer. Ophth. Soc., 1893. Woods: Annals of Ophth. and Otol., 1894.

[2] Beitr. zur prakt. Augenheilk., Berlin, 1876.

leukoma of the right cornea and phthisis bulbi of the left eye.

2. Rivaud-Landrau[1] has published a case of complete destruction of the cornea from ophthalmia two days after birth.

3. Magnus[2] found ophthalmia fully developed five hours after birth. The membranes had ruptured almost three days before. Both corneæ had gray infiltrations at birth. Large opacities remained.

4. Paryschev's[3] case, in which the membranes ruptured three days before birth. There was typical ophthalmia when the child was born, and extensive opacities of the corneæ. The purulent secretion contained many gonococci. He advises prophylactic vaginal irrigation after the membranes have ruptured, using a solution of mercuric chlorid (1 : 2000 or 1 : 3000) for this purpose.

5. Krukenberg[4] demonstrated a child which presented swelling of the eyelids and conjunctiva, and cloudiness of the right cornea, when born. Gonococci were found in the conjunctival secretion (not purulent) and also in the vagina of the mother. The rupture of the membranes had taken place two days before birth.

6. He mentions that Keller had a similar case, in which the rupture of the membranes had occurred seventeen hours before birth.

7. Feis[5] reports a case of marked ophthalmia neonatorum (great swelling of both upper lids and profuse yellow, watery secretion) without involvement of the corneæ. There were gonococci in numbers. The mother had no vaginal discharge, but a greenish-yellow cervical secretion adhered to the examining finger (latent gonorrhea). The vagina was frequently irrigated with a 1½ per cent. solution of carbolic acid. The author believes that the infectious cervical secretion was carried to the eyes of the infant by the examining finger. In Haussmann's *Bindehaut-infektion bei Neugeborenen*, 1882, mention is made of

8. Galezowski's case of ophthalmia neonatorum noticed at birth, but the details are not given.

9. Feis cites a case that occurred at the Vienna "Findelhaus" in 1863. The child was born with both corneæ destroyed and the irides prolapsed, in consequence of intra-uterine ophthalmia.

10. Haussmann[6] reports a case in which redness and swelling of the conjunctiva were noticed at birth, the affection disappearing in several days; the rupture of the membranes had not occurred prematurely. The author assumes that the pathogenic substances had made their way through the unbroken membranes.

11. Winckel[7] has reported a case of ophthalmia in a child when born, but we have been unable to get the details.

Bellouard[1] reports the following cases as occurring in the practice of Dianoux, Guilbaud, and himself.

12. Dianoux had a patient suffering with vaginal blennorrhea for several months. Fearing ophthalmia neonatorum, he used injections of sublimate (1 : 100) and of silver nitrate (1 : 100). Labor was rapid. On account of the numerous injections it was impossible to tell when the membranes had ruptured. One hour after birth a few drops of a 2 per cent. solution of silver nitrate were instilled. In ten hours the lids were tumefied, but the affection was rapidly checked by treatment.

13. Dianoux was called to a case of ophthalmia neonatorum which had made its appearance on the day that the child was born. The inflammation greatly increased, and one cornea was much damaged. The mother had had a vaginitis, but it had been treated with care. The membranes had broken two days before birth.

14. Guilbaud saw a case in which the membranes had ruptured sixty hours before birth. The child's eyelids were enormously swollen when it was born, and pus and blood were discharged when the lids were opened. They were treated with boric acid, and later with silver nitrate, and were completely cured. The mother had had a vaginitis.

15. In one of Bellouard's cases labor began at 3 A.M., at which time the bag of waters was found intact. At 11 A.M. the child was born. Repeated examinations were made by students. At the moment of birth the lids were found agglutinated, red, and swollen. A 2 per cent. solution of silver nitrate was instilled. At 4 P.M., thick greenish pus was discharged. Recovery was rapid. The mother had leukorrhea for four months before labor.

16. In another case of Bellouard's rupture took place nineteen hours before birth, at the beginning of labor. At birth the lids were red and swollen, and three hours later there was an abundant discharge of a thick fluid. The eyes were entirely closed. The mother had a severe vaginitis, and enormous vegetations. In these cases frequent examinations had been made during labor.

17. In Looten's case[2] the child was admitted to the hospital one day after it was born, at which time there was chemosis of the eyelids that had probably existed for at least twenty-four hours. The cornea of one eye was involved.

18. Fers[3] reports the case of a child, born fifty-four hours after rupture of the membranes, presenting well-marked blennorrhea of both eyes. Gonococci were discovered in the secretion.

19. The following case came under my observation at the "Maternité" of Baltimore. The mother had chancroids and venereal warts. The child was born July 2, 1890, the mother having been in labor for two days. The membranes broke at 6.15 A.M., and the child was delivered at 9 A.M. of the same day. Silver nitrate (2 per cent.) was in-

stilled immediately; within one hour after birth, when the child was washed, the nurse noticed that there was pus in the eyes, and called the attention of the resident physician, Dr. S. H. Allen, to it. I was called on the following day, and found the eyes discharging a yellowish fluid; there was not much swelling; there were opacities of both corneæ, but no ulcers. The treatment consisted in the application of cold and silver nitrate. The child was discharged July 30th, with large opacities of both corneæ.[1]

These nineteen cases are all that I have been able to collect, though using great care; this indicates that intra-uterine infection is very rare.

When did infection occur in these cases? Probably soon after the rupture of the membranes, the infectious material being carried in most cases by the finger of the examining physician or midwife. In seven cases the rupture occurred between forty-eight and seventy-two hours before birth. In seven the time of rupture is not stated; in two it occurred from seventeen to nineteen hours before birth, and in one (Bellouard, 1) it took place within eight hours; in another (Haussmann) it is said to have occurred shortly before delivery, while in my own case it appeared to have taken place only three hours before. Haussmann assumed that the pathogenic agents passed through the unbroken membranes. Bellouard thinks that there was a lateral rupture of the membranes, sufficiently large to admit the entrance of the poison, but not permitting the entire fluid to escape, for the bag was distinctly felt eight hours before the child was born. In my case the inflammation had passed through the period of incubation, and there was pus in the conjunctival sacs at birth; infection must have occurred at least twenty-four hours before birth, and twenty-one hours before the amniotic fluid escaped. I am unwilling to accept Haussmann's explanation,[2] that the poison passed through the unbroken membranes, and think it more likely that there is an error of observation, *i.e.*, that there was an earlier rupture than stated, with probably partial discharge of the fluid, as is assumed by Bellouard.

As the infection occurs at varying lengths of time before delivery we should expect to find the inflammation in different stages of development. This is actually the case. Thus, in some the inflammation began to show itself a few hours after birth, and in one the eyes were completely destroyed at birth.

The number of eyes that were thus lost by corneal involvement is exceedingly large. The result is stated in fourteen of the cases; in five of these the cornea escaped, but in nine corneal opacities resulted. Though the total number of cases reported is not large, still we do not hesitate to call this form of ophthalmia exceedingly dangerous. We would attribute the virulence of these cases in part to the prolonged contact of the eyes with the poison. In cases in which infection occurs during the short time that it takes for the head to pass through the vagina, the contact may be very short, and then the eyes are almost always immediately washed. The duration of contact in cases of intra-uterine infection may be hours or even days.

It is interesting to consider the question of prophylaxis as applied to these cases. The application of Credé's method would appear to us to be of service in those cases only in which the infection was very recent. Bellouard ascribes much benefit to it in Cases 12 and 15, but it was used in my case without benefit. Bellouard suggests the use of vaginal injections, especially in those cases in which the membranes rupture early. Pareschev used injections of mercuric chlorid (1 : 2000 or 1 : 3000) without benefit. Feis made frequent irrigations with one-and-a-half per cent. solution of carbolic acid, without preventing the appearance of the inflammation at birth; Dianoux applied mercuric chlorid (1 : 100) and silver nitrate (1 : 100) frequently in the form of vaginal injections, besides Credé's method, and still the ophthalmia developed ten hours after birth. Aside from the danger of the use of such strong solutions of mercury, it appears that their benefit is far from having been proved, though they would seem to be indicated.

This form of ophthalmia neonatorum is fortunately very rare, as is shown by the meager number of cases reported, as well as by the fact that such large statistical tables as those of Credé appear to be unaffected by it.

---

[1] Since writing this paper the following notes have been received from Dr. Edith Eareckson, of this city: She was called to attend a colored girl in her second confinement, March 17, 1893, and was informed that the membranes had ruptured eight hours before she arrived. The labor was tedious, there being a face-presentation, and the child was not born till seven hours later. At birth the eyelids were much swollen and tightly closed. When forced open to use Credé's preventive, silver nitrate, muco-pus jetted out. The eyes were washed as thoroughly as possible with a solution of mercuric chlorid, and a 1 per cent. solution of silver nitrate was dropped in. Nine hours later much pus was again found in both eyes. The condition of the corneæ was not noted. After the fifth day the case passed out of her treatment, and nothing further was heard of it.

[2] This assumption is also made by Nieden, Zehender's Monatsbl., 1891, p. 353, to explain the appearance of an ophthalmia in an infant born in unbroken membranes. The child was taken out of the sac by the physician with the greatest care. And yet the eyes became inflamed in twenty-four hours in the characteristic manner, though gonococci were not to be found in the secretion. Nieden assumes that the amniotic fluid was infected by the diffusion of a poisonous substance which was capable of producing an inflammation similar to that due to the gonococci, though less intense and more rapidly cured. We are, however, unwilling to accept this explanation, and believe that direct infection took place, even though much care was exercised.

LOCAL ELECTROLYSIS AND ZINC-AMALGAM CATAPHORESIS IN MALIGNANT AND NON-MALIGNANT TUMORS.[1]

By G. BETTON MASSEY, M.D.,
OF PHILADELPHIA,
PHYSICIAN TO THE GYNECOLOGICAL DEPARTMENT OF HOWARD HOSPITAL AND TO THE SANATORIUM FOR DISEASES OF WOMEN AND DISEASES OF THE NERVOUS SYSTEM.

Before reporting the three cases on which this new treatment of morbid growths is mainly based I must explain what I mean by local electrolysis and zinc-amalgam cataphoresis, and also advance reasons for my belief that these methods, either separately or together, present important advantages over cutting operations in certain cases of benign vascular growths and incipient carcinomata.

Local electrolysis means simply that the electric decomposition of the tissue-salts is confined to a localized area by the approximation of the poles. If both poles of a galvanic current be placed in the morbid tissue quite near each other, the bulk of the current will be concentrated within the tissue immediately between them, and but little will traverse the outside healthy parts. In practice they should not be further apart than from a half to one inch, though this depends entirely on the strength of the current to be used and the size of the growth. So placed, an enormous current may be employed to dissolve a morbid tissue without affecting the surrounding tissues, the parts having been chilled by a spray or otherwise, if sensitive, rendered anesthetic. The surgical possibilities of such currents are quite remarkable. All the salts and liquids of a given growth lying between the points become a prey to such a current, the watery contents being turned into oxygen and hydrogen gases, and the complex salts into solutions of acids and alkalies. This is, of course, attended with a material rise of temperature, but nothing like charring. If the tissue subjected to the process is soft and vascular or juicy, there will be very little left between the poles after the gas has been given off, but the acids and alkalies dissolved in a turbid liquid remainder. If the tissue is tougher and more fibrous, a gristly residue will be found which can be detached or left to be detached by nature.

The strength of current required to destroy tissue in this way depends altogether on its concentration at the active spot. A minute reproduction of the process occurs when we apply but two or three milliampères to the papilla of a hair-sheath or to a mole on the skin ; but to dissolve completely tissues between two or more needles a half-inch apart requires a current of at least from 400 to 700 milliampères.

Whether this portion of my method has any advantages over a cutting operation in removing malignant or non-malignant external growths depends upon circumstances. It is clearly inapplicable to any growth within the body unless it is situated in a drainable natural cavity, as a considerable quantity of detritus must drain away. It also presents the disadvantage of not permitting healthy tissues to be united at once over the seat of the removed growth, a procedure, however, that is often of doubtful utility, as it frequently covers up portions of the disease that failed to be removed. The advantages of the method over the knife are, on the other hand, by no means inconsiderable. It is absolutely bloodless, no matter where applied, thus enormously conserving strength after operations notoriously bloody ; the edges of the undestroyed tissue remain non-absorbent, lessening risk of sepsis ; and finally there seems to be some property in the galvanic current to cause a retrogression of the whole of a benign growth, even when but a portion is directly acted on, as in the Apostoli treatment of fibroids, and the ordinary treatment of moles and other small skin-tumors.

If the growth be a benign one, the application described will probably cover the whole of the active treatment. If it be malignant, on the contrary, the second portion of the method—zinc-amalgam cataphoresis—is employed, a procedure of great value in radically removing all remaining traces of a still localized carcinomatous growth.

Zinc-amalgam cataphoresis is electrically monopolar, the single active electrode, which is always positive, being applied to the cavity left by the removal of the greater portion of the growth, while the indifferent or negative electrode, in the shape of large conducting pads connected together, is placed on any convenient part of the body. The active electrode is a freely amalgamated zinc surface of one or two square centimeters area, which is held successively against all portions of the bottom and edge of the excavation. From 150 to 300 milliampères are sufficient, the pain being controlled by cocain in solution placed in the excavation beneath the electrode, to be conveyed into the tissues simultaneously with the nascent zinc oxy-chlorid and mercury, which are dissolved from the electrode by electrolysis.

By this procedure we search out and destroy all remaining spurs and paths of infection in the contiguous unhealthy and healthy tissues, the current seeking vascular and cellular paths of less resistance by preference in its journey to the other pole ; and to the lethal effect of the current we add the well-known lethal effects of nascent compounds of mercury and zinc. The surface of the amalgamated zinc electrode is consumed in the process—the mercury as well as the zinc—producing a mixed infiltration of the immediate polar region that is readily detected by the eye. Low organisms in the immediate neighborhood of the electrode quickly succumb, and the antiseptic value of the procedure is shown in the correction of any odors that may have accompanied the carcinomatous discharge. That the action is not confined to the immediate neighborhood of the electrode was well demonstrated in one case in which the zone-like base of a carcinoma was observed to lose its induration and shrink in places distant at least an inch from the contact-point.

---

[1] Read before the Philadelphia County Medical Society, January 9, 1895.

The applicability of the first portion of the method—local electrolysis—to a benign growth was shown in the following case:

Case I. *Large intra-uterine cystic fibroid destroyed piecemeal by repeated applications of bipolar electrolysis, resulting in a satisfactory cure.*—Mrs. D., a nullipara, aged thirty-nine years, was referred to me by Drs. Hemminger and Bixler, of Carlisle, Pa., in September, 1892. Six or seven years previously Dr. Hemminger had discovered an intra-uterine growth, the lower portion of which was later found to be projecting from the dilated os, giving rise to pain and hemorrhage. Efforts to remove the growth by the écraseur were made by Dr. Hemminger, but, owing to its extensive internal attachment and great vascularity, only the projecting parts were removed. When I first saw the patient the tumor was nearly the size of an adult head, the upper limit being even with the navel. The mass was symmetric in shape, soft, and semi-fluctuating. Examination showed the os fully dilated, through which projected a portion of the tumor the size of a fetal head. Around this projecting mass several fingers could be swept, showing freedom from adhesion to the uterus for three inches anteriorly and about six inches posteriorly. The mass was evidently a vasculo-cystic fibroid situated within the cavity of the uterus and attached to the uterine walls throughout three-quarters of its periphery. It was spongy, but very tough, bled easily, and gave rise to a copious watery leukorrhea. The conditions presented by this growth, particularly its cystic degeneration, absolutely contra-indicated the ordinary Apostoli treatment of fibroids, on account of the danger of producing sepsis. I accordingly attempted its removal by morcellement, using the scissors, the dull scalpel, and the fingers, but was compelled to desist, owing to the frightful hemorrhage. In this dilemma the possibilities of localized destructive electrolysis occurred to me, and it was begun by the use of a bipolar instrument having four prongs, two to each pole. These prongs were buried in the projecting portion of the tumor and a current of 700 milliampères turned on for six minutes. This dissolved quite a hole in the morbid tissue, making the spot too hot for the finger. The procedure was repeated daily without hemorrhage or marked discomfort, as fresh portions of the growth were pressed down by the contracting uterus the possibility of sepsis being guarded against by a continuous douche for an hour or more after each application. Three months were consumed in the eradication of the tumor in this way, though it doubtless could be done in a second case in a third of the time, the final examination showing nothing but a roughened spot on the anterior wall of the contracted uterus. External measurements now showed the upper limit of the uterus two-and-a-half inches below the navel. The cavity was capacious.

A letter from Dr. Bixler, dated February 26, 1894, stated that the patient was quite restored to health, complaining only of prolapse of the vaginal walls, the latter doubtless due to the descent into the pelvis of a uterus that had so long been within the abdomen. The cavity was still large, and there was some thickening of the walls on both the right and left of the uterus. The os would admit only the first joint of the finger.

In November, 1894, two years after the patient's admission, her husband called and reported that she was in good health.

Case II. *Sarcoma of tonsil and soft palate cured by local electrolysis followed by zinc-amalgam cataphoresis.*—W. H. L., a blacksmith, aged thirty-eight years, was also referred to me by Dr. Hemminger, February 17, 1893. Five years before he had had an abscess of the left ear. Two years before being seen by me the left tonsil was found to be the seat of a tumor. He had recently been sent to the Hospital of the University of Pennsylvania, where he says malignancy was diagnosticated and an operation urged, which he declined.

A tumor about the size of a goose-egg filled the pharynx, involving the tonsil and the soft palate, and threatening suffocation. Liquids only could be swallowed, and these with increasing difficulty.

The patient was placed on monopolar negative puncture with a current of from 30 to 60 milliampères daily. But little progress being apparent at the end of a week, the parts were cocainized, and on two occasions subjected to bipolar local electrolysis with a current of from 200 to 350 milliampères. The separation of the eschar that resulted was accompanied by some pain and reaction, but as the place healed it was seen that but a small portion of the growth remained. The man did not return for further treatment until more than a year had elapsed, during which he seemed to be well. At this time, however, a renewal of the growth occurred, and it was about the size of a peach-stone when he was readmitted to the Howard Hospital. During this second treatment zinc-amalgam cataphoresis was mainly employed, the treatment lasting six weeks, and being carried deeply into the base of the growth. A complete cure resulted, and at the examination of the parts six months later a healthy scar only was to be seen.

Case III. *Inoperable carcinoma of the groin greatly relieved by zinc-amalgam cataphoresis; death from erosion of femoral artery and vein.*—Col. H., aged sixty-two years, was sent to me by Dr. A.W. Knox, of Raleigh, N. C., in the summer of 1893. One year before he had noticed a lump in the left groin. When first seen the tumor was the size of a large walnut, of a bluish color, and firmly attached by a broad base to the deeper parts of the thigh. It was situated just below Poupart's ligament, and lay immediately over the femoral artery and vein, and was apparently attached to the latter, though the exact location of the artery was uncertain owing to the general induration.

At the patient's request it was decided to make a tentative use of electricity. The central and projecting portion was accordingly destroyed by local electrolysis, making a slight cavity into which a solution of cocain was poured. Into this the blunt amalgamated zinc-electrode was pressed and daily applications of the cataphoresis made, with currents averaging 150 milliampères. The immediate effect of the application was to whiten the edge of the growth in contact with the electrode, the whitened coating peeling off later. The indurated ring and base that now represented the growth was about three inches wide. Under constant applications the whole of this was gradually destroyed and replaced by healthy granulations, except the center of the base, where the close proximity of the large artery rendered the applications unwise. At the end of three months the diseased area had been contracted to the size of a five-cent piece, but there was a deep cavity extending down to the great vessels, where it was thought to be unsafe to apply the current. The patient had increased twenty pounds in weight, and though he had been brought on a stretcher, he was now able to walk a half-mile or more. During the continuance of this improved condition, however, the artery suddenly gave way one day at the bottom of the untreated spot. Drs. Thos. S. K. and T. G. Morton were called in consultation, and the former tied both artery and vein, which were found thoroughly infiltrated with carcinomatous material for some distance upward into the abdomen. Gangrene of the limb supervened, followed by death two weeks later.

An estimate of the value of the method in these three cases must be comparative, as cases similar to each are usually subjected to other methods, removal with the knife being the favorite. Hysterectomy in the first case would, of course, have involved removal of the ovaries also. Both this and removal of the uterus itself were avoided entirely, no natural structures being even injured, and the time required in the treatment was probably not longer than that necessary to recovery from the effects of abdominal section. In the second case the bloodless removal of a sarcoma of the palate was followed by a treatment of the neighboring parts that I hope will render the patient less liable to a return of the disease. The third case was, of course, a failure to cure or to preserve life, yet it is thought that life was prolonged by the very evident curtailment of the growth and improvement of health. Comparisons were hardly possible, however, as an operation had been refused by one surgeon as useless.

212 South Fifteenth Street.

THE RELATIVE AGE-OCCURRENCE OF COLLES' FRACTURE—A TABLE OF NINE-HUNDRED-AND-EIGHTY-EIGHT CASES.

By CHARLES A. POWERS, M.D.,
OF DENVER, COLORADO,
LATE SURGEON TO ST. LUKE'S HOSPITAL AND TO THE CANCER HOSPITAL, NEW YORK.

In June, 1890, while serving as surgeon to outpatients at the New York Hospital, my attention was called to the large number of boys and young men who came under my care suffering with fracture at the lower end of the radius. A considerable proportion of the fractures were transverse; many were oblique, and had the typical deformity of the "Colles'" fracture. In many instances the injury had been diagnosticated as a sprain, and the patient had been told to use the limb, when pain and disability, with, perhaps, increasing deformity, led the sufferer to seek advice at the hospital. So many boys and youths presented this lesion that I passed in review the cases which had previously been under my care at the Chambers Street Hospital, and gained the impression that the percentage occurring at this age is greater than is generally thought or taught. I believe that I am not wrong in saying that it is generally supposed that the Colles' fracture occurs most often in women, and in women between forty and sixty years of age.

An exact definition of Colles' fracture is not easily given. Originally the term was applied to those lesions at the lower end of the radius accompanied by the typical "silver-fork" deformity. This deformity may be pronounced, or it may be so slight as to be practically unnoticed. As a rule, the more oblique the line of fracture the greater the deformity. It is not infrequently seen, however, in cases in which the bony lesion seems on palpation to be practically transverse. In the greater number of cases the line of fracture is between one-half inch and one inch above the articular surface. It may be less or more than this. It has seemed wise to me, therefore, to include under the head of "Colles'" all fractures, completely traversing the radius below a point one-and-one-half or two inches above the articular surface.[1] This would include, of course, diastases.

As I have said, my attention was so strongly called to this frequency in boys that I looked up the cases treated at the Chambers Street Hospital between December, 1878, and June, 1888,[2] and those in the out-patient department (second surgical) of the New York Hospital, between January, 1888, and June, 1890, the latter date representing the time at which the list was made. The result of this investigation is shown in Table A and the accompanying chart. It is seen that in males nearly one-half (201 cases out of 590) occurred in the second decade, while in females the greater number (132 out of 398) were found in the first decade. Attention is called to the proportion occurring in males, 590 cases out of 988.

---

[1] 1½ inches in children, 2 inches in adults.

[2] If I remember rightly, this period was taken as representing the incumbency of Dr Bull as chief surgeon. During a considerable portion of this time I served on the staff as house-officer and out-patient surgeon. The date of January, 1888, re-

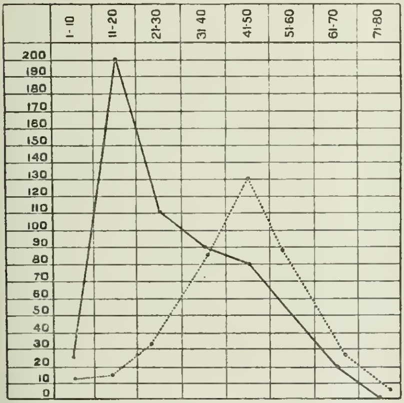
CHART.



The continuous line represents males, the dotted line females.

In this connection it may not be amiss to state the character of the districts which furnished these cases. The House of Relief of the New York Hospital (formerly known as the Chambers Street Hospital, now occupying the new building known as the Hudson Street Hospital) is situated in the lower part of New York, and draws its out-patients from a large and crowded tenement-house district, as well as from the immense factories and workshops and traffic-laden streets. The out-patient department of the New York Hospital in Fifteenth Street is recruited largely from the tenement-houses of the West Side. It is very possible that an equal number of these accidents occurring in private practice might furnish charts of a different character. My own private practice has, however, furnished a number of cases in patients under twenty years, of which the following may serve as an illustration:

In September, 1894, I was asked by Dr. J. W. O'Connor, of this city, to see W. E., a boy of eight years, who gave a history of having sustained an injury to both wrists some four weeks previously. He had been seen by the family physician, who had made a diagnosis of sprain, and had treated the case accordingly. Pain, disability, and deformity had led the parents to take the lad to Dr. O'Connor, who had recognized the true nature of the lesion. On examination both wrists were found the seat of Colles' fracture. The deformity was typical in each instance, the lower fragment being thrown back and to the radial side. The line of fracture seemed oblique, just above the carpal articulation. There was firm union. Ether was administered, and vigorous attempts made to refracture, but without avail. In view of the moderate degree of the deformity osteotomy was thought inadvisable.

I have seen other similar cases in which a diagnosis of sprain had been made. It is not improbable that what would seem, after union had taken place, to have been an oblique fracture was originally a transverse diastasis, but that early use, before union, has thrown the lower fragment backward. In this way patients who return to work too early may occasion a marked deformity.

We should, then, carefully examine young people with injured wrists for fracture. The diagnosis can generally be made, if seen early, by obtaining false motion and a soft crepitus. In some cases, however, it may be difficult. As Stimson says: "In difficult cases, fat people and children, without displacement, it may be made upon the existence of a well-defined transverse line of tenderness, or pressure on the dorsum of the radius, deepening of the transverse folds on the palmar aspect of the wrist, loss of power in the limb, and history of the case." The only table with which I am able, at this time, to compare my own is that quoted by this author (*Treatise on Fractures*, p. 323). In this the fractures of the entire radius are given:

presents my appointment at the New York Hospital, and the cases there are from my private notes. A few cases in private practice are included.

The accompanying chart represents cases which returned to the hospital for treatment. A considerable number in addition had a single dressing applied, and failed to reappear. I do not assume that it is to be accepted as conclusive, and simply offer it as a contribution to a subject of much interest, and hope that surgeons who have access to the records of a considerable number of cases may be led to place their statistics on record.

A CONTRIBUTION TO THE STUDY OF OCCIPITO-POSTERIOR POSITION OF THE VERTEX.

BY JOHN O. POLAK, M.D.,
OF BROOKLYN, N. Y.,
INSTRUCTOR IN CLINICAL OBSTETRICS, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, AND THE LONG ISLAND COLLEGE HOSPITAL.

THE notes forming the basis of this paper are the result of a detailed study of twenty-nine cases of vertex-presentation, with the occiput to the back. In each particular instance the diagnosis was confirmed by other physicians after labor was fully established. A brief analytic study of the cases in question shows that twenty, or more than two-thirds of the entire number, rotated to the front, unaided by any manual interference whatsoever, and were delivered normally, with the occiput under the pubes. Of the nine in which spontaneous rotation did not take place, one was complicated by a prolapsed cord, demanding immediate podalic version and extraction. Another occurred in a pelvis having a conjugata vera of but three-and-a-half inches. In this case the occiput was twice manually rotated to the front and axis-traction forceps applied, but all efforts at delivery failed. Internal podalic version under complete narcosis was then elected, easily accomplished, and a successful extraction followed.

Of the seven cases not already considered, three were forceps-operations at the superior strait, with the head but partly engaged. In the remaining four the head had descended to the pelvic floor, with the occiput in the hollow of the sacrum. In all of these instrumental cases, save one, the occiput remained persistently to the back; hence the frequent occurrence of tears in the pelvic floor. These lacerations of the vagina, levator, and perineal body were immediately repaired, special care being taken to approximate the deep muscular structures. Union by first intention occurred in 85 per cent. of the cases operated upon. In but one case was the child stillborn. From the foregoing facts it will be seen that a large majority of posterior positions of the occiput are delivered without the obstetrician's interference, after anterior rotation has taken place. In cases ending thus favorably there is but little added danger to either mother or child. Spontaneous rotation may occur at the superior strait, in the cavity of the pelvis, or on the pelvic floor. From a considerable experience in midwifery I am led to believe that this malposition—for such it is—is of much more frequent occurrence than is generally conceded by most authors, as many of these posterior cases remain unrecognized, owing to the difficulty in diagnosis during the early stages of labor. Again, a large percentage rotate to the front unaided, and are recorded as anterior positions; hence the statistics on this subject are of little value.

An existing disproportion between the head and pelvis is not infrequently met with, preventing proper flexion and engagement, so that dystocia follows, and operative delivery is very often too late to be successful; hence the need of early and accurate diagnosis. Furthermore, the forceps should never be applied until such relations have been carefully determined and possible malpositions corrected. To recognize these conditions after labor is established and a caput formed presents no little difficulty; hence I urge that when there is doubt as to the exact relation that a head bears to a particular pelvis, the patient be chloroformed and the aseptic hand passed into the uterus. This procedure will at once end any such uncertainty. With the hand thus introduced improper flexion of the head may be rectified or the occiput may be manually rotated to the front. It is well to remember, if such rotation be attempted, that it is necessary not only to rotate the occiput, but also to turn the body to the front. This is best accomplished by grasping the posterior shoulder with the internal hand and turning the dorsum to the front; external aid facilitates this manipulation. Early diagnosis and postural methods in this class of malpositions are frequently all that is necessary to terminate labor normally. As rotation takes place at the brim, in the cavity, or on the pelvic floor, so the treatment of each individual case will differ as to the stage of progress in the mechanism.

At the brim (before the head has engaged) the employment of postural methods frequently results in the normal termination of labor. The patient should be placed in the left or right latero-prone position, depending on whether the child's dorsum and occiput point toward the left or the right side of the mother. In one of the cases making the basis of this paper, use of the Trendelenburg[1] posture aided very materially in preserving the normal mechanism. This position offers all of the advantages of the genu-pectoral without the discomforts of the latter to both physician and patient. Should these methods fail, manual rectification or podalic version may be elected. The former procedure deserves consideration when the pelvis is ample, and the dorsum, as well as the occiput, can be rotated to the front. This failing, or should the occiput, after being once turned anteriorly, again rotate to the back, complete podalic version should at once be instituted, not waiting until the amniotic fluid has entirely escaped, and the operation be complicated by a spastic uterus.

---

[1] As suggested by Dr. Fry, of Washington, in the management of mento-posterior cases, May, 1894.

Should any disproportion exist between the head and the pelvis, version may be elected. The extraction of the after-coming head through a flattened pelvis of slight degree is more easily accomplished, by reason of the overlapping of the parietal and underriding of the occipital bones, than the delivery of the fore-coming head under like circumstances. The application of forceps to a head floating about at the superior strait, whether of an axis-traction model or not, is a procedure that deserves the condemnation of careful obstetricians.

In the cavity of the pelvis (when the head has entered the superior strait and is descending, the occiput being shunted to the back by the incline of the levator-ani muscle) rotation may be promoted by keeping the patient in the latero-prone position, having her lie on the side toward which the occiput points. Since beginning this paper I have had two opportunities to utilize a method suggested by Penrose in the management of mento-posterior positions, *i. e.*, the whole hand is introduced into the vagina, the palmar surface corresponding to the position of the occiput. The palmar surfaces of the fingers act as a lateral inclined plane, shunting downward, forward, and inward, while the thumb pushes the sinciput upward and backward, promoting perfect flexion and rotation. This manipulation should only be employed during the pains. Should impaction occur, the axis-traction forceps may accomplish delivery, the head rotating during its descent. I must take issue with the few who forcibly rotate the occiput to the front while the head is well down in the pelvic basin, as at this stage simultaneous rotation of the shoulders is not apt to occur without a dangerous amount of torsion of the neck. When delivery is found to be impossible because of impaction of the occiput in the hollow of the sacrum, symphysiotomy or craniotomy may be elected according to indications.

With the head on the pelvic floor (at the vaginal outlet) the occiput can, in a very large proportion of the cases, be rotated to the pubes "by backward pressure with the fingers against the anterior temple, combined, if necessary, with forward pressure upon the occiput." Should this method fail, rotation may usually be accomplished with a short pair of straight forceps.

Forceps to a posterior vertex as such, with the head on the pelvic floor, is not a difficult operation, though the mechanism and direction of traction must be very closely observed.

Short, straight forceps accomplish delivery most readily. The traction is made directly forward until the root of the nose is immediately behind the pubic arch. The line of traction is then changed to the third position, perfect flexion of the head being preserved by upward pressure against the sinciput with the thumb, while a finger of the same hand in the rectum aids in shelling out the head by dislodging the occiput.

CLINICAL MEMORANDA.

ERYSIPELAS AS A COMPLICATION OR SEQUELA.

BY J. R. JOHNS, M.D,
OF DENVER, PA.

THE importance to the physician of a knowledge of the inherent pathologic proclivity of a given patient, aside from any present disease, cannot be too strongly emphasized. Heredity, though losing ground as a clinical factor since the advent of germ-pathology, must not be underrated. Cachexy or diathesis may be obscure, yet none the less powerful in shaping pathologic processes when intercurrent disease has lowered the system's vital tone. Co-existent with and interdependent upon the malady we are called upon to treat, this deep-seated morbid trend determines the erratic course of disease, it may be causes a fatal issue or simply retards convalescence, all the time probably unrecognized. Important among such tendencies, not to speak of obvious pathologic states of the same, are struma in the young; and in the adult pulmonary tuberculosis, malaria, and that to which special attention is here called, viz., erysipelas.

Since the advent of influenza, five winters ago, I have observed several persons in whom erysipelas occurred as a complication or sequel, the primary affection always being atypical. In all these cases the persons were subject to recurrent attacks of erysipelas.

I propose to detail three distinct attacks that occurred in the same person, giving prominence to the features alluded to.

M. R., forty years of age, the mother of six children, was portly, but had, in general, good health. Independent of the malady in question she enjoyed the immunity from disease of the average of her age. She was prone to have an occasional attack of erysipelas, always of some part of the head. So was her mother, and also her mother's mother. Previously to my meeting her she had two or more attacks.

The first attack to which attention is called occurred during the epidemic of influenza, in January, 1892. In common with the rest of the family she contracted the disease, of a mild type. When convalescence was expected she took to bed with a chill, marked fever, and profound constitutional depression. The local lesion appeared on the hairy scalp; but was, however, insignificant when compared with the systemic disturbance. Being in the eighth month of pregnancy, premature labor was feared; and, indeed, painful contractions occurred at intervals during thirty-six hours. This was successfully averted, however, by the use of quiet and opium.

In due time convalescence came, and later a perfect child was born at full term. Though the woman was in labor for twenty-four hours, and required forceps to effect the delivery, convalescence after labor was uninterrupted and complete.

In August of the same year she was taken with acute tonsillitis, for which the usual remedies proved speedily efficacious. Febrile action had ceased, and the tonsils had again apparently returned to their normal condition, when, on the fifth day, there was an unusual development in the case, marked by chill, hyperpyrexia, violent headache, and great swelling of the fauces. At once the tonsils showed a thick white coat in patches. The question of immediate isolation seemed paramount; but suspecting an invasion of the old trouble I deferred the diagnosis to the sixth day, meanwhile placing certain restrictions upon the rest of the family.

On the sixth day high fever, great depression, at times a muttering delirium, foul breath, approximating tonsils, and difficult respiration were the symptoms that marked the case. The question was: Erysipelas of the fauces or diphtheria, which? Knowing the morbid proclivity of my patient, and taking into consideration the shade of the swelling, her age, the mode of attack, and the facility with which the coating was detached from the tonsils, I pronounced the case one of erysipelas of the fauces. The developments in the case confirmed my diagnosis. Sustaining treatment, soothing local applications, liquid food, quiet and rest, were followed by complete recovery.

In connection with this case I recall the following episode: The hamlet was greatly alarmed. Many feared an outbreak of diphtheria, and scrupulously kept aloof. One old gossip, a large-hearted soul, was a frequent caller, and even ventured to supplement treatment. On returning to the quiet bed-chamber one morning I at once detected more than the fetor of the patient's breath. Upon inquiry I was informed that Mrs. M. had applied a poultice which was known to be highly valuable in such cases. Her poultice consisted of freshly-dropped hog manure. I need not add that as soon as enough light and vent could be had this "animal extract" was hurled to the street below.

During February of the past year I was called to deliver this woman of her eighth child. Labor was normal, but convalescence was slow and discouraging. Tenderness and sharp pain centering in the right inguinal region, accompanied by a mild degree of fever, appeared the first day and continued four days. Calomel and sodium bicarbonate, āā gr. ss., with acetanilid, gr. iv, repeated every two hours, removed all pain. The stools became frequent, liquid, and bloody; and continued so in diminishing degree for several days. The temperature became normal on the fourth day. At this time there was a slight chill and return of fever, which continued one week. With the return of the fever she began to complain of soreness of the tongue. This was mainly on the right side, where a broken molar tooth had irritated the organ. Her continued weakened state kept me on the alert for an outbreak of erysipelas which had now appeared in the form of erysipelatous glossitis. On the second day after the chill, as I entered the room, the patient informed me that the old trouble had returned; "for," said she in muttered speech, "I can taste it." Inspection confirmed her diagnosis. The tongue was uniformly involved and now completely filled the mouth. The lesion was strictly confined to the tongue. Treatment similar to that employed in the attack of erysipelas of the fauces was instituted, and in the second week she was again found mending.

My knowledge of this proneness to recurring attacks of erysipelas in this patient, as in others to which I can but allude here, enabled me to employ early those supporting measures upon which life depended. How to explain the etiology and the apparent heredity of this proclivity in the light of accepted pathology are questions for others.

CARCINOMA OF THE RIGHT MAXILLARY ANTRUM.[1]

BY ARTHUR H. CLEVELAND, M.D.,
CLINICAL PROFESSOR OF LARYNGOLOGY, MEDICO-CHIRURGICAL COLLEGE;
SURGEON TO THROAT, NOSE, AND EAR DISPENSARY,
PRESBYTERIAN HOSPITAL, PHILADELPHIA, PA.

R. T., a colored woman, whose age was not exactly known, but who was probably in the neighborhood of sixty years old, was first seen at the clinic of the Presbyterian Hospital on March 13, 1893. She gave a history of nasal trouble of over three months' duration, during which time she had been under constant treatment elsewhere, and had been several times cauterized. There was stoppage of the right side of the nose, with considerable discharge, both muco-purulent and crusty. Coincidently with the nasal trouble, she said, she began to have pain in the right ear, with dulness in hearing. The pain extended to the back of the neck, and there was stiffness of the jaw, with pain on opening the mouth widely. The patient claimed to have had no nasal trouble previously to this attack. The family history was hard to obtain and unsatisfactory.

Examination showed the right nostril filled with mucopus. The lower turbinate was somewhat enlarged, but the middle turbinate was much enlarged and inflamed. A posterior view was not obtainable. The pharynx was not much congested. The right membrana tympani was considerably thickened; the left thickened and opaque, and in the posterior lower segment, below the malleus handle, were some chalk concretions.

As the last "burning" had been but recently done I attributed the inflammation to that, and prescribed a weak alkaline wash, to be used twice daily.

On March 29, 1893, the patient returned, still complaining of the discharge and stoppage. The inflammation seemed to have decreased, and attached to the right middle turbinate posteriorly was what appeared to be a large raspberry polyp. Its removal by the cold snare was followed by copious epistaxis, not, however, sufficient to be alarming. The nostril was plugged with gauze for a short time, but this was soon removed.

The sensation afforded by the snare while cutting through the growth was peculiar and hard to describe, but very characteristic. It was as if the tissue was emphysematous and the fibers brittle.

---

[1] Read (by invitation) before the Laryngological Section of the College of Physicians, December 11, 1894.

The polyp showed nothing peculiar except that there were some evidences of inflammation and small connective-tissue trabeculæ running through it.

Microscopic examination was not made.

On April 3, 1893, the woman again returned with the discharge persistent. Examination showed the middle turbinate still swollen and very much inflamed. There had been one or two attacks of epistaxis, not of long duration, but very free while they lasted. The aural pain still persisted. She was again given a nasal wash, hoping that a few days would reduce the inflammation and allow more extended examination.

The patient did not return after this, and on the first of May the dispensary nurse looked her up, finding her at home and in bad condition.

She was immediately brought to the hospital and admitted to Dr. H. R. Wharton's ward. Through his kindness I was enabled to see her there. The first visit confirmed to my mind the diagnosis of carcinoma, which I had before guardedly made. There was swelling of the entire right side of the face; the right eye was prominent, and the lids edematous, with considerable conjunctivitis and discharge, owing to inability to close them. The pain in the ear was still severe and persistent. The temperature varied slightly from 99°. Operation was thought inadvisable, and the patient gradually sank and died from exhaustion on May 12th.

The autopsy was made by Dr. H. W. Cattell, and from his notes, supplemented by later examination of the specimens, which I was privileged by the family to remove, we obtain the following:

A large extra-dural mass involved the neighborhood of the sphenoid bone superiorly, extending anteriorly to the crista galli and the orbital plate of the frontal bone on the right side. Posteriorly it extended nearly to the anterior margin of the petrous bone. The sella turcica seemed broken down and incorporated in the mass, which was of a soft consistence, and was infiltrated with pockets of sanious pus. The right optic foramen was much enlarged and the bones disorganized. The eye on that side was diseased, shrunken, and discharging pus. The optic nerve in its backward course penetrated the mass of new growth and soon became unrecognizable. The cavity of the tympanum was not affected, the bones and membrane being intact. Below, the right maxillary antrum was filled with a gelatinous mass mixed with pus. The bony walls were apparently sound except posteriorly, where they were eroded. The lower turbinate was not enlarged anteriorly, but posteriorly had reached a large size. The middle turbinate was much involved, being enlarged in its whole extent. The septum was not affected. The growth and position of the mass pointed to an origin in the antrum. Microscopic examination of a specimen from there showed it to be a carcinoma.

108 S. SEVENTEENTH STREET.

Meharry Medical College.—The nineteenth annual commencement of Meharry Medical College, the ninth of the dental department and the sixth of the pharmaceutic department of the Central Tennessee College, were held on February 5th, at Nashville, Tenn. There were twenty-nine graduates in medicine, two in dentistry, and five in pharmacy, and the interesting feature is that all were colored men.

A CASE OF FORMATION OF A NEW LID BY TRANSPLANTATION OF SKIN WITHOUT PEDICLE (WOLFE'S OPERATION).[1]

BY HOWARD F. HANSELL, M.D.,
OF PHILADELPHIA,
CHIEF OF CLINIC OPHTHALMOLOGICAL DEPARTMENT, JEFFERSON MEDICAL COLLEGE HOSPITAL, ADJUNCT PROFESSOR OF DISEASES OF THE EYE, PHILADELPHIA POLYCLINIC.

IN February, 1893, X. Y., a married woman of intemperate habits, applied at the Out-Patient Eye Department of the Jefferson Medical College Hospital, during the service of Prof. William Thomson, for relief of an extremely disfiguring deformity of the upper lid of the left eye. Several months previously, while temporarily unable to control her movements, she fell down a short flight of steps, striking the left side of her face against a hard substance and breaking the skin. Erysipelatous inflammation and abscesses followed. After recovery the upper lid of the left eye was completely everted and held fixed in its new position by a firm, dense, horizontal, linear cicatrix, which united its ciliary border to the skin beneath the supra-orbital margin, entirely obliterating the normal exterior lid-surface. The conjunctiva was thickened, indurated, and congested from constant exposure to wind and atmospheric impurities. The cornea remained clear, vision good, and no disturbance of the function of the eye was found. While undecided as to the best method of operation, I had the opportunity, through the courtesy of Dr. G. E. de Schweinitz, to examine a case in which he had transplanted a piece of skin without a pedicle after the removal of an epithelioma involving the entire lower eyelid. (*Transactions American Ophthalmological Society, 1894.*) The result had been so satisfactory after the lapse of nearly a year that I determined to attempt a similar operation. Accordingly, a few days later, under ether, I loosened the ciliary border of the lid from its abnormal attachment, excised the cicatrix into which the skin of the upper lid had been transformed, restored the lid to its normal position, and retained it by stitching the margins of the two lids together. Thus the denuded surface was stretched and its folds obliterated. The surface thus exposed measured about 20 mm. vertically and 25 mm. horizontally. From the inner aspect of the thigh a flap of skin 35 by 40 mm. and as deep as the subcutaneous tissue, but not including it, was removed, having previously been thoroughly cleansed by ablutions with warm water and soap and made aseptic by mercuric-chlorid solutions. The excised portion of skin was subjected to no intermediate treatment, but was at once transferred to its future site, and carefully spread, so that there was an overlapping of about 5 mm. on every side. The free border was then sutured in the adjacent healthy parts, and the whole covered with a moist mercuric-chlorid dressing, and held by a roller bandage. The wound on the thigh healed, without interruption, by granulation. Union between the transplanted and the underlying tissue, fostered by the immovable and continually expanded position in which the lid was held by the sutures, seemed to commence from the outset, and grew more firm daily. The overlying edges shrivelled and blackened, and, in a few days, were trimmed off and the sutures removed. The result is excellent. At present, ten months after operation, the only noticeable defects are the slightly lighter color of the flap, as compared with the adjacent skin, and the presence of a few fine hairs. The patient suffers no inconvenience whatever, although, on account of a shrinking of a third of the original area of the transplanted tissue, she cannot completely close the commissure.

---

[1] Exhibited before the Section of Ophthalmology of the College of Physicians, November, 1894.

Contraction of the graft, which is the only disadvantage of operating by Wolfe's method, does not seriously modify the result when performed on those portions of the body where there is naturally a redundancy of skin and connective tissue, since its place is supplied by neighboring parts. Death of the epithelium, noticed by some operators, was not a feature in my case, and, if it occurred, escaped observation. The superiority of this over operations with a pedicle lies in the achievement of a good result with a minimum deformity, and is applicable especially to exposed surfaces.

NEW DEVICE.

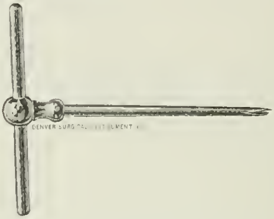
A NEW INSTRUMENT FOR MARKING THE SKULL IN BRAIN-OPERATIONS.

By CLAYTON PARKHILL, M.D.,
OF DENVER, COLO.,
PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF COLORADO, VISITING SURGEON TO ST. LUKE'S AND THE ARAPAHOE COUNTY HOSPITALS, MEMBER AND EX-PRESIDENT OF THE COLORADO STATE BOARD OF MEDICAL EXAMINERS, ETC.

While operating in a case of brain-tumor several years ago I was making use of a small drill to mark the skull in conformity with the measurements that had been made upon the scalp. To my surprise, and at the same time chagrin, the instrument passed directly through the skull and was driven into the brain. On removing the button of bone I found that, owing to the pressure of the tumor the skull had atrophied until it was scarcely thicker than an egg-shell. This experience, however, taught me that the instrument was not the proper one for making the markings. Larger drills are objectionable on account of the laceration of the soft tissues. Again, I have been embarrassed on several occasions by the fact that it was difficult to distinguish the marks made on the skull by the point of a drill from the foramina in the bone. I have had the Denver Surgical Instrument Company make for me an instrument for this purpose, which is shown in the accompanying cut. It consists of a shaft 9 cm. in length with a cross-bar handle 8 cm. The end of the shaft is divided into two portions or legs, one projecting beyond the other to the extent of 1 mm. This longer leg is made triangular, like the stylet of a trephine. The shorter leg, which is separated by two mm. from the longer one, is pointed, and its right side is knife-edged.

To use this instrument it is thrust through a small puncture in the scalp made with a scalpel. By turning it from left to right the longer leg becomes engaged in the bone and the short leg swings about this point as a center and describes a circle. The action is identical with that of a carpenter's compass. The knife-blade of the short leg is made in order that it may cut the periosteum as it is turned.

The advantages in using this instrument are: 1. It is thrust through a very small, clean-cut wound in the scalp. 2. The instrument is sufficiently large, so that it would be pure carelessness if it were thrust through even the thinnest skull. 3. It makes a mark that cannot be mistaken for anything else.



I have used this instrument in quite a number of brain-cases in the last two years, and I have found it to be eminently satisfactory. I take pleasure in commending it to the profession.

MEDICAL PROGRESS.

Successful Trephining for Right Hemiplegia with Epilepsy.—Wood and Cotterell (*British Medical Journal*, No. 1775, p. 10) have reported the case of a girl, three-and-one-quarter years old, who presented weakness and inability to use the right hand, arm, and leg, together with a history of epileptic attacks. At the age of one year, the child had fallen from the top of a hay-rick, without immediately bad results. In the course of a few weeks, however, what appears to have been an epileptic seizure occurred. She fell, became unconscious, and lost power in the right arm and leg. Some six months later, two other seizures of similar kind occurred, and several again one year after this. The convulsive movements always commenced in the right thumb and fingers. On examination it was found that the left supraparietal region was distinctly flattened and sloping straight away from the vertex, the parietal eminence appearing to be pushed down and becoming more abruptly prominent than upon the opposite side. The eyes presented no lesion. The right arm was shorter than the left and cold and bluish-red in color. The movements were confined to flexion at the elbow-joint, which was necessarily limited by the general rigidity of the limb. The thumb was held across the palm of the hand, and, like the fingers and wrist, remained strongly flexed. The leg was rigid, the foot inverted, and walking could only be accomplished with great difficulty and with support.

An exploratory operation was decided upon and a semicircular flap, four inches long, was reflected up from the left parietal region. The periosteum was raised over an area of about two inches, the center of which corresponded to the middle of the flattened region. A disc of bone was removed by means of a three-fourths inch trephine from a point corresponding to the middle of the fissure of Rolando. The opening thus made was enlarged with cutting forceps. The dura mater was opened, and directly underneath there appeared a small cyst filled with serous fluid, situated apparently under or between the layers of the arachnoid. The dura mater was thickened over the cyst and adherent in places. The adhesions were separated and two pieces of the external wall of the cyst were removed. The dura mater was stitched up, except at the lower angle, a catgut drain inserted and the wound closed. The child was collapsed after the operation, but quickly rallied. The wound healed by first intention, except in the track of the drain. A large amount of cerebro-spinal fluid escaped through the dressing for three or four days, but the wound was completely healed in the course of nine days after the operation. The child rapidly improved, notwithstanding attacks of whooping-cough and chickenpox. Six weeks after the operation the child was able to walk without support. The hand could be opened spontaneously, and no fits had occurred. The improvement steadily continued until there remained very little of the hemiplegic condition.

Removal by Celiotomy of a Sarcoma of the Right Kidney from a Child a Year-and-a-Quarter Old.—GÖRL (*Centralblatt für die Krankheiten der Harn- und Sexual-Organe*, 1894, No. 10, p. 530) has reported the case of a boy, who, when eight months old, began to fail in health, and in whom the mother observed a sense of relative hardness upon the right side of the abdomen. There was also constipation, and to this was ascribed the abnormal physical condition. When the child was fourteen months old, a tumor was distinctly visible. This gradually increased in size, and there became superadded pain, emaciation, and debility. The tumor was oval, elastic, and movable, both laterally and vertically. It was easily separable from the liver, and did not move with the diaphragm in respiration. It could readily be felt to originate from the posterior wall of the abdominal cavity. The urine presented no abnormality, but the diagnosis of malignant growth of the kidney was made. Operation was undertaken when the child was sixteen months old, and the symptoms had existed for eight months.

In view of the not inconsiderable size of the neoplasm, its removal through the peritoneal cavity was undertaken. After the abdominal cavity had been opened by an incision along the outer margin of the right rectus muscle, from the costal margin almost to Poupart's ligament, the peritoneum covering in the anterior surface of the tumor was incised and the peritoneal covering dissected off with the fingers. The growth was now brought to the abdominal opening and its posterior coverings split. The ureter and the renal veins were ligated, and the hilus divided. The tumor was removed, and the abdominal wound closed and appropriately dressed. The operation occupied but a quarter of an hour, and was well borne by the little patient. The excretion of urine was distinctly increased, and so continued for four weeks. At first the secretion contained some blood.

The further course of the case was favorable, so that the sutures could be removed on the tenth day, when primary union was found to have taken place.

For the protection of the line of the abdominal wound a binder was worn for a number of weeks. The condition of the child rapidly improved, and the patient appeared perfectly well five months after the operation. He was able to run around eight weeks after the operation.

The removed neoplasm was somewhat pear-shaped, and had a diameter of five-and-a-half inches. At its superior pole were the remains of the kidney. Histologically, the new growth presented the appearance of a small round-celled sarcoma.

Two Cases of Hysterical Blindness in Males, with Recovery.—BARKAN (*Festschr. zum 25 Jähr, Jubilaeum des Vereins Deutscher Aerzte* 1894) has reported two cases of complete blindness in hysterical men, with recovery. One occurred in a mine-engineer, thirty-two years old, in whose hands a jar of tomato-catsup exploded in the process of opening. The patient was struck in the face and eyes by fragments of glass, and, in attempting to reach a source of water for the purpose of removing the blood, his foot slipped, and he fell and lost consciousness for some hours. On returning to consciousness he was unable to see. There was also complaint of severe occipital pain. Under treatment with morphin, and blisters to the temples and behind the ears, light-perception and a slight degree of vision were restored. The eyelids were closed spasmodically, so that cocain had to be employed to facilitate examination. It was found that the right eye had been wounded at the corneoscleral margin, where the iris had become adherent, so that the pupil was pear-shaped, and reacted but slightly to light. The media were clear and the eye-ground normal. The left pupil was slightly dilated and reacted doubtfully to light. The media and fundus were also normal.

In the absence of organic change sufficient to account for the loss of sight, the diagnosis of hysteria was made and a favorable prognosis given. Injections of strychnin, gr. $\frac{1}{25}$, were prescribed, together with applications of the constant current, and iron, nutritious diet, systematic out-door exercise, cold sponging and massage. The black covering that had been used to protect the eyes was replaced by dark glasses. Improvement soon set in, but was temporarily interrupted by an interruption in treatment. This was, however, subsequently resumed, and the patient progressed to final recovery.

The second case occurred in a steward, thirty years old, who, after the ingestion of medicine furnished by a druggist for the relief of pains in the hips and arms, at once noticed impairment of vision. Several months previously vision in the right eye had been lost, and subsequently that in the left eye became dull. There was also severe and constant pain in the left eye and left half of the head, aggravated by the recumbent position and flexion of the head. The right cornea presented a central cicatrix and a turbidity of the capsule of the lens in a corresponding situation, both of which were ascribed to an ophthalmia during infancy, followed by corneal ulceration and perforation. The media and fundus were normal in both eyes. Improvement soon followed applications of the constant current.

Subcutaneous Torsion of the Spermatic Cord for Prostatic Hypertrophy.—RICHMOND (*British Medical Journal*, No. 1780, p. 339) suggests as a substitute for orchectomy for the relief of prostatic hypertrophy *bistournage* or subcutaneous torsion of the spermatic cord, with the view of cutting off the blood-supply of the testis and causing its subsequent atrophy.

THERAPEUTIC NOTES.

The Treatment of Diphtheria with the Antitoxin.—WITTHAUER (*Therapeutische Monatshefte*, 1895, Heft 2, p. 67) has reported the employment of the antitoxin in the treatment of thirty-six cases of diphtheria, with five deaths. In addition the following solution was employed as a gargle: Solution of ferric chlorid, 5 parts; glycerin and absolute alcohol, each 7½ parts. Of this fifteen drops were added to a glass of water.

At a recent meeting of the Ophthalmological Society of the United Kingdom JESSOP (*British Medical Journal*, No. 1780, p. 304) reported two cases of diphtheric conjunctivitis successfully treated with the antitoxin. The first was in a boy, nineteen months old, who presented membrane upon the upper and lower palpebral conjunctiva of the left eye, and a patch of membrane on the left side of the uvula; a lymphatic gland over the parotid was enlarged, and the urine contained albumin. Three injections of Klein's antitoxin were given, one-and-one-half drams in all. The membrane disappeared in five days, and left no conjunctivitis or other conjunctival change. In the second case, in a male child, eight months old, there was membrane on the palpebral conjunctiva of both eyes; the parotid lymphatic glands were enlarged, and there was a muco-purulent discharge from the nose. Two injections of Klein's antitoxin, one dram in all, were given, and the membrane disappeared in four days. Examination of the membrane in both cases disclosed the presence of diphtheria-bacilli.

Of 330 children received at the Hôpital des Enfants Malades in Paris, 258 of whom were recognized as diphtheric and were treated solely with the antitoxin and tonics, 31 died (12 per cent.). Of the fatal cases, eight died within twenty-four hours of admission and without having had time to receive the treatment.—*Lancet*, No. 3728, p. 377.

At a recent meeting of the Royal Medical Society of Vienna MONTI (*British Medical Journal*, No. 1781, p. 385) related that he had treated 25 cases of diphtheria with the antitoxin, with but a single death.

HEIM reported that of 27 cases of diphtheria similarly treated from October 6 to November 4, 1894, six died (22 per cent.), while among 236 cases treated during the year previously by other methods the mortality was 52.4 per cent. The average mortality for ten years ending with 1894 was 51.1 per cent.; the lowest rate was 25.9 per cent. in 1886, and the highest 58.7 per cent. in 1892.

UNTERHOLZNER stated that he had treated 37 cases between October 11, 1894, and January 10, 1895, with the serum, with eight deaths, five of which occurred within twenty-four hours of admission. He presented tables showing that among 31 cases treated with the serum there were eight deaths (25.8 per cent.), while among 36 cases treated without serum there were twenty-four deaths (66.6 per cent.). The second group included many mild cases.

KOLISKO (*Wiener medizinische Blätter*, 1895, No. 5, p. 75) reported the results of 75 post-mortem examinations of children dead of diphtheria and treated with the antitoxin. There was no doubt of the favorable influence of the treatment upon the diphtheric process. If a sufficient dose was employed and a reasonable time had elapsed, rapid and equable exfoliation of the membranes was to be observed. The changes were most striking in cases of descending croup. The membranes were readily detached, because the administration of the antitoxin checked the formation of the toxins upon which the production of fibrin depended. The varying severity of the process was not believed to be an expression of various forms of the disease, but rather of various stages, as the process may have been long unobserved in circumscribed areas. The degenerative changes in the heart and the renal affections did not differ from those of ordinary occurrence. The local reaction at the seat of injection was so variable as to suggest differences in the fluid used. As direct results of the injection a streptococcous abscess and a phlegmon were observed. Cultivation-experiments in a case of erythema yielded negative results.

Among 30 cases of diphtheria treated by RAUCHFUSS (*Lancet*, No. 3729, p. 451) with the antitoxin, 19 recovered and 11 died (36.6 per cent.), while among a similar number treated during the same period with other measures the mortality was 52 per cent.

ESCHERICH (*Münchener medicin. Wochenschr.*, 1895, No. 7, p. 155) has treated 51 cases of diphtheria with the antitoxin, with five deaths (9.5 per cent.). Three of the fatal cases were in a hopeless condition when they came under observation.

The Treatment of Eclampsia.—GUBAROFF (*Centralblatt für Gynäkologie*, 1895, No. 5, p. 127) recommends a mode of treatment that he has successfully employed in six cases of eclampsia, three of which presented grave symptoms. The treatment consisted in the administration of narcotics, principally morphin in moderate but frequently repeated doses (gr. ¼ subcutaneously about six times in the twenty-four hours, according to the amount of urine); enemata of chloral, and only during operative procedures (including catheterization) mild chloroform-narcosis. All measures tending to stimulate the activity of the skin or to replace this vicariously were freely resorted to. These included warm baths, though but infrequently; moist warm packs constantly, and several times daily friction with a solution of vinegar, salt and alcohol, and dry hot-air baths. In all cases the bowels were freely evacuated as early as possible by means of salines (equal parts of sodium sulphate and magnesium sulphate). Besides, careful attention was given to the functions of the kidneys. These were stimulated by the administration of milk and mineral waters, and the application of heat in the lumbar region over the kidney by means of a large rectangular hot-water bag. Only in one case was bleeding practised.

For Coryza in Children.—

℞.—Atropinæ sulph. . . .	gr. $\frac{1}{600}$.
Morphinæ sulph. . . .	gr. $\frac{1}{60}$.
Quininæ sulph.	gr. $\frac{1}{10}$.
Strychninæ sulph. . . .	gr. $\frac{1}{240}$.
Acidi arseniosi	gr. $\frac{1}{240}$.—M.

Ft. pil. To be taken every hour until dryness of the throat is felt, and then followed by minute doses of apomorphin every two hours.

—TAYLOR, *Phila. Polyclinic*, vol. iv, No. 7.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM, IN ADVANCE $4.00
SINGLE COPIES 10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM . . . 7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MARCH 9, 1895.

THE APOTHEOSIS OF HYSTERIA AND WHIMSICALITY.

ONE of the functions of a medical journal is to notify its readers of the appearance of new and important medical works, and so deeply are we impressed with the transcendent importance of one such book recently issued, that we believe we are doing a great service to medicine by a somewhat extended and free advertisement of it. It is by W. A. DEWEY, M.D., a late professor of materia medica, an editor and associate editor of numerous medical journals, an author and associate author of several medical works, a member of many medical societies. The last title the learned author gives himself on the title-page of his book is simply this: "*Homœopathic, etc., etc.*," which reminds one of a drug catalogued by the New York homeopathic druggist, SWAN, as "Omnia." The book to which we call especial attention is entitled: *Essentials of Homœopathic Therapeutics, being a Quiz Compend upon the Application of Homœopathic Remedies to Diseased States*, and is published by Bœricke & Tafel, Philadelphia, 1895.

"One of the grand cardinal features of homœopathy," says the author in his preface, "and one little understood by the allopathic school, is the fact that any drug in the entire homœopathic materia medica may be a remedy in any diseased state. It is, therefore, evident that the preparation of this work entailed no little difficulty, etc." In view of the infinite multiplication of "remedies," and of the numerous different "potentizations" of each, together with the literally bewildering multiplication of "symptoms" or "provings," this modest qualifying reservation is very appropriate, as otherwise all the books that have ever been printed could not contain the possible "Application of Homœopathic Remedies to Diseased States."

Before passing to the subject-matter of the volume we cannot forbear a word of criticism as to the strange fatality that makes it impossible for our homeopathic friends to write sentences according to the fundamental rules of English grammar. In reading this remarkable work, for example, we seem to hear the echoes of some half-forgotten *patois* in which philologic crudities, barbarisms, and grammatic impossibilities vie in vain with pseudo-scientific whimsicalities and medievalisms. The very contractions used of the names of drugs make one smile, as, *e. g.*, croton tig., carbo veg., Lyc., carbo an., Kali bich., etc. How can one who knows that the word *blepharospasm* itself means twitching of the lids speak of "a blepharospasmus twitching of the eyelids?" To one not conversant with occultism, the works of Mme. BLAVATSKY, or the strange use of language by the homeopaths, a large number of the sentences are absolutely devoid of meaning. One wonders how symptoms can be called "female symptoms," or "male symptoms," what sentences without verbs can signify, what the personification of drugs betokens, etc. Of these grammatic peculiarities, of which certainly every second sentence is an illustration, we quote a few examples that have attracted the attention:

> The sensations are throbbing, which is intense and sudden, and the pains are apt to cease as suddenly as they appeared.
>
> Stramonium has visions of animals coming towards him from every corner.
>
> It is a hoarse, croupy cough, but withal a loose edge.
>
> The patient clutches the air; sometimes a stupor, which, if aroused out of, they strike people.
>
> The child appears to have but one bowel extending from mouth to anus.
>
> The diarrhea of Thuja is a chronic diarrhea traceable to vaccination forcibly expelled like water from a bung-hole.
>
> What drug has nausea at the thought of food? even mention food and he vomits.
>
> Gulping up of burning water.

The patient is excitable, restless and fidgety. They are awkward and clumsy.

Where does Kali bich. come in?

What drug has a great deal of depression about his chest, is tearful and discouraged, and fears that he will go into decline?

Patient thinks she will go crazy, is suspicious, has visions of rats, etc.; is conscious, but can't help it.

Stannum has characteristically falling of the womb during hard stools.

In glancing through this volume one is struck by the almost maniacal revelling in the nasty. Every possible discharge or excretory product of the body (our author would call it "a secretion from the body") is described, with a vividness of language, and with a fond enumeration of the morbid varieties and of their unexampled filthiness; the catalogues of Rabelais pale before the telling word-pictures of our author. This is undoubtedly due to the habit of treating symptoms rather than to a distinctly Rabelaisian type of mind however. This fact may also explain why *spermatorrhea* has the consideration of nearly three pages, whilst *peritonitis* has but half a page; why diseases of women require nine pages, whilst tuberculosis and "phthisis" combined require but three.

But this enumeration of symptoms—what awful absence of the sense of humor does it show, the perfect solemnity with which this apotheosis of hysteria is set down! A person, we suppose, has taken an infinitesimal amount of "carbo veg." and whatever morbid whims pass through his fancy for days are supposed to be "provings" of the drug, although any amount of carbo veg. in the shape of toasted bread may be eaten at other times.

Thus "*phosphorus* has evening hoarseness, while *Causticum* has morning hoarseness," "*lilium* is worse in the afternoon, *sepia* in the forenoon." One drug produces a sensation in the right arm, another in the left arm. One produces headache over only the left eye, or pain in the left ovary, headache upon one side of the head ("the pains following the course of the sun"), etc.

The explanation of a number of national traits is suggested by the assurance that among the mental symptoms of gelsemium is mentioned, "does not seem to care whether school keeps or not;" among those of Platina, "the patient is proud and haughty; looks down upon everybody with disdain; everybody seems beneath her;" among those of Baptisia, "He thinks he is scattered about, and he must move to get his pieces together again;" in children chamomilla produces the very human trait: "want to be carried about, and want different things, and when they get them throw them away dissatisfied." Our neighbors, the Britishers, have often wondered why we Americans "like to sit with the feet on the table." They may now understand that it is due to "the effect of carbo veg. on the liver." Profanity, it would logically seem, might be lessened by restricting the sale of nitric acid.

In private practice we have often been told by patients that they had been given medicines for cataract for years by homeopathic practisers, and lo! here, Anno Domini 1895, is phosphorus commended therefor!

It is little wonder that the animosity against the "allopath" is so great that a drug having a general exercising or purifying effect is recommended as "the first remedy to use if the case comes from allopathic hands."

Quotation is better and more just to the talented author than any setting forth of his teachings in our own poor words. We therefore give free permission to scissors, to wit:

What drug has amenorrhea from getting feet wet?

What drugs have backache worse while sitting?

Arsenicum lacks the tingling of *secale*, and wants to be warmly wrapped up. *Secale* wants to be cool, and lacks the anxious tossing about and restlessness of *arsenicum*.

Mention three drugs having colic from a fit of anger.

All muriates have crumbly stools.

What drug has convulsions in children from rich food?

What drug has a cough that is worse when strangers are present?

In the diarrhea of aloes the patient loses confidence in his sphincter.

Arsenic wants little and often, *apis* thirstless. The bloating in *apocynum* is on the side on which he lies. *Arsenic* in the extremities. *Apis* under the eyes.

What drug has pain in the right eye as if it were pushed out of the head, worse near a warm stove?

What are the symptoms to China in dyspepsia?

What drug especially desires oysters?

What drugs have the symptom that the patient has to loosen the clothing after eating?

When a hemorrhage is due to a strain or misstep cinnamomum is to be given.

Belladonna is relieved by being propped up in bed, while *sanguinaria* has relief from lying down. *Belladonna* was not so marked.

What drugs have headaches relieved by copious urination?

What peculiar symptom has Oleander in the head? Headache relieved by looking sideways.

Arsenic has hypertrophy of the heart, resulting from climbing high places.

"Castoreum the secretion from the beaver" (sic) is recommended for "women who are pretty near the hysterics."

Where do the pains of Croton tiglium go upon nursing? To the back.

What drug has the symptom that the patient predicts the hour of death?

What drugs have hasty speech and hasty drinking?

What symptoms has anacardium? It produces a weak memory; he imagines he hears voices, and another condition is a propensity to swear; it is mental condition, and it does not exist as a condition of low morals.

What other drug produces a disposition to swear? Nitric acid?

The *staphisagria* child is impetuous and irritable, reminding one of *chamomilla.*

What are the mental symptoms of sepia? The patient is low-spirited, cries readily; weak memory; there is sadness and irritability; it will not do to find fault with her; there is also perfect indifference, especially to household affairs and to her own family; the patient is easily offended; she dreads to be alone, wants company, but has an aversion to her own friends.

How is *Sepia* distinguished from *Pulsatilla?* Both have weeping, anxiety, peevishness, and are ill-humored; but *Pulsatilla*, only, has the mild, clinging disposition calling for consolation; she makes her grief known and asks sympathy. The *Sepia* patient is worse from gentle exercise, but is relieved by violent exercise.

What drugs have the symptom that the patient has to think how words are spelled? (*Spelling-reformers will take notice!*)

What are the mental symptoms of sulphur? Patient fears she will not be saved; there is anxiety about her own soul, but perfectly indifferent about the souls of others.

With Hepar sulph. the patient is especially sad in the evening, and does not wish to see members of his own family. (*And thus at last is an explanation and a cure assured for a sad social custom!*)

With antimonium crudum the crossness of children is increased by washing them with water.

With gelsemium the patient does not seem to care whether school keeps or not.

What is the Graphites temperament in general? Sad, fat, fair and constipated.

What drug has the symptom that the soul feels as though it were freed from the body?

What drug has special action on the right wrist?

The *Natrum carb.* patient gets very nervous during thunder storms and hides in the cellar. This nervousness is said to be due to the electrical condition of the atmosphere acting on such patients.

Pulsatilla is mild, tearful and whimsical. *Sepia* is depressed, easily excited and irritable. *Pulsatilla*—blondes. *Sepia*—brunettes.

What drug cures nymphomania from worms crawling into vagina and there causing irritation.

What drugs have especially sensitiveness to coitus?

What are the menses of calcarea carb?

What drug has menses flowing only in daytime when about on feet?

What drug has early and scanty menses in tall slender females?

Medicine is a serious study and the medical life is proverbially a solemn one. Perhaps we have quoted too extensively from our valued author, but his teachings we trust may be found at least temporarily a good "regular" dose antidotal of the gloominess of our calling. The richest and most perfect humor in the world is the unconscious variety, that wherein the most profoundly earnest joker dreams least of all things that he is producing a work that will inspire most uproarious laughter in thousands of readers.

But after the laugh the return to work! After the fun the payment of the bills! Thereupon come the indignation and the disgust—the thought that it is for the encouragement of this sort of nauseating drivel that our aristocratic society gives "charity balls;" for this that our legislators vote hundreds of thousands of dollars of the people's money; this gibbering ghost of medieval medicine it is that an intelligent and discriminating people call the "new school!"

STATE APPROPRIATIONS FOR PRIVATE HOSPITALS.

Before the Pennsylvania State Legislature the various charitable institutions have laid their applications for appropriations for the years 1895 and 1896. The amounts asked for by hospitals of the third class, that is, hospitals owned and controlled by private corporations, are

For the year 1895	$1,446,211 93
" " " 1896	1,019,500 00

About one-half of this is for new buildings or for removing debts of mortgage, and one-half for maintenance.

When an individual endows a bed in a hospital he has a right to send anyone there, at any time, to occupy such a bed. When the State gives a grant of $50,000 it virtually endows ten beds, yet does not possess any right to such beds. The only place a poor incurable tuberculous or other invalid needing the attention a hospital can give has a right to go is the Philadelphia Hospital, and here, alas, there is but little room for him.

The private hospitals often obtain their appropriations only through strong lobbying, and if a charity has a "pull" it can get almost anything it wants.

A few individuals organize a hospital, largely and principally for their own benefit, and then obtain appropriations from the Legislature, by which they can erect costly buildings and bring themselves into prominence.

If institutions are to receive State aid, they should be under State control, and where it is found that over-lapping exists, that one institution can do the work of two, the other should be dropped from the State list.

The following Philadelphia hospitals are represented in the applications:

Name of hospital.	Amount asked for 1895.	Amount asked for 1896.	Amount received in past six years.
Hahnemann	$67,000	$50,000	$73,546
University	50,000	50,000	135,000, 4 yrs.
“ Maternity	5,000	5,000	
“ Veterinary	5,000	5,000	30,000, 4 yrs.
St. Timothy's	12,500	12,500	7,000, 2 yrs.
Kensington, for Women	13,500	5,000	5,000, 2 yrs.
Polyclinic	25,000	25,000	87,000
Jefferson	50,000	50,000	130,000
Woman's	25,000	25,000	25,000
Howard	2,500	2,500	
Medico-Chirurgical	82,500	82,500	170,000
Rush Hospital	75,000	75,000	
West Phila., for Women	12,500	12,500	
Women's Homeopathic	17,400	17,400	67,000
Children's “	17,000	17,000	8,000, 2 yrs.
St. Cristopher's	5,000	5,000	
Philad'a Lying-in Charity	7,500	7,500	15,000
Southeastern Dispensary	2,500	2,500	
Orthopedic	23,500	23,500	30,000
Maternity	8,000	5,000	15,000
Gynecean	20,000	15,000	85,000
Wills Eye	10,000	10,000	40,000, 4 yrs.
Samaritan	30,000	30,000	
German	10,000	10,000	40,000, 4 yrs.
Hospital for Incurables	20,000	20,000	

It will be noticed that all of the foregoing institutions, with the exception of Wills Eye Hospital, which is in trust of the city, are strictly private concerns. They are not obliged to render account to any public official. The funds received may or may not be applied to the purposes for which they are asked.

The Governor has but recently stated that economy is necessary in the affairs of the State. Let the Appropriation Committee turn to the private hospitals first.

We want a State Hospital for Epileptics and two or three for tuberculosis, but let these be managed by the State as the hospitals for the insane are.

We hope that the medical profession of Pennsylvania will enter a protest against indiscriminate grants to private charities, and ask that State moneys be applied to institutions under State control.

EDITORIAL COMMENTS.

As to Physio medicalism.—We have received two letters concerning "errors" and "falsehoods" contained in the little historic article of Dr. Nichols on Physiomedicalism in The Medical News of February 9, 1895. Although we are not responsible for the opinions expressed in signed contributions to our columns, we shall make brief answer to these criticisms editorially, because of our lack of space to accommodate both our critics and our contributor with replies and again replies. As to matters of opinion and of medical philosophy, they are beyond our present province or interest; as to matters of accuracy in the statements of fact, they may be summarized as follows:

1. That Thomson's views were accepted by good and intelligent men of "cultured Boston" and New England, and, therefore, the views were true, and the man was "a man of talents and skill." The acceptance of an opinion by all the John Quincys, Batemans, etc., of New England, makes the opinion neither true nor false. If our critic will go to Boston to-day, he will find Harvard professors and the "bluest blood" of that quack-ridden city consulting clairvoyants, faith-curists, layers-on of hands, mesmerists, and spiritualistic mediums. Thus, as the critic would agree, instead of the aristocratic profession of faith proving the truth of the faith, it may only prove the intellectual degeneracy and *bêtise* of the aristocrat.

2. One of Dr. Nichols' critics (Dr. William H. Cook, of Chicago) takes exception to the statement that lobelia, capsicum, and the vapor-bath are the chief remedies of physio-medicalism. The information was derived from the writings of Alva Curtis and of Dr. Cook himself. (*Review of Allopathy and Defense of Physio-medicalism.*)

3. The critics contend that lobelia is not a poison, etc. The statement that lobelia is a poison is, we believe, the view generally held by such authorities as Bartholow, H. C. Wood, etc., Ringer to the contrary notwithstanding. Numerous references to fatal cases of poisoning may be found in the *Catalogue of the Army and Medical Library.* The statement that botanic practisers have been repeatedly tried and convicted for manslaughter caused by lobelia-poisoning was based on an article in the *Medical Times and Gazette*, of London, volume viii (1854), page 491, in which is given a list of thirteen cases of lobelia-poisoning in the three or four years preceding, in six of which a verdict of manslaughter was rendered. It was not said that there were ever any convictions of this character in America, nor do we think there have been.

Untruthful Clinical Histories.—If one asks a reputable English physician in reference to the statistics and character of a certain compatriot whose name and writings are well known, one is greatly puzzled at the fact that he gets no satisfactory answer. The one questioned probably stares silently into the air, with a tormenting expression of quizzical self-restraint, or he says something about his ignorance concerning the gentleman mentioned, or he cautiously hazards a word or two as regards the weather. After receiving such "answers" several times, if one "bulldozes" a friend and promises absolute secrecy, one may finally get a solution of the mystery in the brutal remark which bursts forth as if from a too-long-restrained reservoir: "Oh! He's an infernal liar! You can't believe a word he says."

Truth compels us to admit that the English by no means have a monopoly of the article in question. Undoubtedly, one must not believe all the vindictive sneers and scandal that is or that may be set going by jealous rivals or personal enemies. Undoubtedly, also, there are entirely too many such malicious stories passed from none too clean mouths to avid ears. But again, undoubtedly, there is one, or, perhaps, there are several specimens of the genus liar in the medical profession. Beyond question, also, these specimens are infinitely better known than they themselves suspect. Very recently a physician read before a large society a paper, since much reproduced and quoted, in which he took decided grounds against the position previously assumed by one whose conservatism, honesty, and scientific quality of mind are beyond question. His opposition was bolstered up by reports of cases. As the reports were read a clinical assistant of the reader, sitting on a back seat with several friends, introduced parenthetic remarks, *sotto voce*, to the effect that one "cured" case had lately returned no better than before the cure, that another had not been buried from the hospital, that yet another had been sent home to die, etc.

Here is concealed a fallacy that more or less vitiates all medical statistics, and induces the undiscerning to repeat an operation or a method of treatment to the cost of the patient and to the shame of the physician. He who in the least falsifies his clinical reports is a criminal against his profession and against humanity.

Phonography in Medicine.—There can be no question that a medical man fortified with an ability to write short-hand possesses a decided advantage over one who lacks this accomplishment. Too much importance cannot be attached to the making of full and detailed clinical records, but the difficulties are numerous and great, particularly in private practice, where the work cannot always be detailed to clinical clerks or assistants. These difficulties can in large measure be overcome if stenographic notes are made at the time of investigation. Further, a recent graduate will find useful application of his phonographic ability in the reporting of lectures or similar work, for which he is likely to have time during at least the early part of his professional career. Good medical stenographers do not exist in excessive numbers, and the remuneration may help tide over a critical period.

The distinguished neurologist, Dr. Gowers, himself an adept and enthusiastic stenographer, has long insisted on the wisdom of medical men educating themselves in phonography. With the aid of others he has organized a Society of Medical Stenographers, which publishes monthly (except during April, August, and September) *The Phonographic Record of Clinical Teaching and Medical Science*, containing stenographic reports of lectures by medical men, and other articles and matters of interest. It is proposed also to issue from time to time supplements containing matters of combined medical and phonographic interest. A list of more than 1800 vocalized outlines of medical terms is in course of preparation for distribution among the members of the society. The *Record* is edited by Drs. Gowers and Taylor. The annual subscription is, for medical men, five shillings; for medical students, three shillings. Dr. Neil, Warneford Asylum, Oxford, Eng., is the honorary secretary.

The Reprint Advertisement.—In partisan politics one of the most disheartening things is not that men can stoop to such scoundrelism as they do, but that the humbuggery is so evident. It depresses one to find, first, that a man can try to play so poor a trick, and play it so poorly; and, second, that there is any considerable number of one's fellow-citizens so stupid as to be fooled by such evident hypocrisy and nonsense. In medicine we have the same causes for wonder. As one takes note, for example, of the tricks of the advertising specialist, he is shocked to think that there are so many *confrères* who can be hoodwinked by such specious buffoonery. There must be many who are taken in, or it would not pay to do it so much.

We have before us as we write a pamphlet purporting to be the reprint of an article published first in a medical journal. The first page is filled with a portrait of the author of the pamphlet, under which appears the name with many and long degrees and titles of the professor, his addresses, office hours, etc. The atrocities of the illustrations, artistically and anatomically, make us wonder if it is not a mistake that even a single copy of the reprint should have found its way into professional hands. Was it not meant for distribution among possible patients rather than among physicians?

Even the Carpet-cleaners are After Us!—Physicians of a large city are receiving the following letter:

> Dear Sir: We beg to call your attention to the enclosed card. Knowing that you are called upon when sickness enters a home, we would consider it a great favor, if, whenever possible, you would mention our name and address to the person in charge of the house, stating that after sickness or death feather beds, bolsters, pillows, and hair mattresses are often soiled, and therefore prejudicial to good health, and the same should be renovated and disinfected. We do this thoroughly by our steam process, removing all impurities, etc., and making the articles equal to new.
>
> On all orders we receive through you, we will gladly allow you 25 per cent. commission, which shall be remitted to you promptly, or accounted for on any work of your own.
>
> Trusting you will consider this favorably we are,
>
> Yours respectfully, ———

Dr. William T. G. Morton.—Among the fifty-three names which are to be inscribed as a roll of honor in the dome of the new chamber of the House of Representatives, in the State House, at Boston, and each of which is intended either to mark an epoch or to designate a man who has influenced the course of events, we note that three were borne by members of our profession. Only one of these three, however, was chosen on account of eminent services to medicine. The name so dignified is that of Dr. William T. G. Morton, who was the prime mover of the experiments which led to the establishment of anesthesia by sulphuric ether as a matter of practice. Of the priceless value of this boon to the human race, it would be superfluous at this day to speak. That the name of the man through whom it came should be held in lasting honor, and given a high place in the list of benefactors to mankind, is but just and right.

The Montefiore Country Home for Consumptives is the name of a new non-sectarian institution to be established in New York for the gratuitous treatment of the tuberculous poor. Mr. J. H. Schiff and Mr. L. G. Bloomindale have each contributed $25,000 for the purpose.

REVIEWS.

A TEXT-BOOK OF THE PHYSIOLOGICAL CHEMISTRY OF THE ANIMAL BODY, INCLUDING AN ACCOUNT OF THE CHEMICAL CHANGES OCCURRING IN DISEASE. By ARTHUR GAMGEE, M.D., F.R.S.
VOL. II. THE PHYSIOLOGICAL CHEMISTRY OF DIGESTION. Pp. 528. London: Macmillan & Co., 1894.

THIS volume forms, like its predecessor, which appeared in 1880, an independent and complete treatise. The first volume, now undergoing revision, was devoted to the physiologic chemistry of the elementary tissues of the animal body. The present, of more practical interest to the laboratory-worker and to the clinician, deals with the physiologic chemistry of digestion, and forms a work based, as the author states, on an original study of the whole literature of the subject, and is intended as "an accurate guide to the advanced student and the original worker, both in the study and in the laboratory."

Dr. Gamgee writes in an attractive style, approaching his subject from the standpoint both of a physiologist and a chemist. He discusses at length not only the physiology of the digestive processes occurring in the body, but also the pathology of jaundice, the pharmacology of the icterogenic poisons and of cholagogues, and the structure and formation of gall-stones. The important intestinal processes resulting from the activities of microörganisms are not omitted, and a description of the formed enzymes, some seven individual species, normally present in the intestines, is included. Stress is especially laid on the little-known fact that, as a result of the same bacterial action, so great is the quantity of organic acids, chiefly lactic, formed in the bowel, the intestinal secretions, from pylorus to cecum, are practically never alkaline, excepting those of the duodenum at the time the pancreatic juice is being most actively secreted. He points out that it is through the agency of these same microörganisms that the bile indirectly owes its antiseptic virtues; the lactic and other acids so formed from the carbo-hydrates, after neutralization of sodium carbonate secreted by the mucous membrane during digestion, liberate from inactive combination a certain amount of bile-acids, so powerful in inhibiting putrefactive intestinal processes. Concerning gall-stone formation, he points out, according to the view of Naunyn, that these are probably the result of an infectious process, and occur through the migration of bacteria from the duodenum, exerting a pathogenic action on the mucous membrane of the bile-passages, this same migration being facilitated by sluggishness of biliary flow. It is shown that the increase of the frequency of gall-stones in the aged is thus indirectly the result of diminution of respiratory activity leading to stagnation of bile in the ducts. He also cites the other important factor, that of atrophy of the unstriated muscular fibers existing in the walls of the bile-passages, this last condition especially leading to formation of concretions without symptoms of colic.

The interesting fact, yet not generally known, is also fully noted that so-called hematogenous or non-obstructive jaundice does not exist, it now being settled that jaundice is always due to obstruction to the normal efflux of already-formed bile. The biliary acids and coloring-matter are both formed in the liver, so that extirpation of that viscus in animals does not occasion jaundice, even under conditions that might be supposed otherwise to produce the falsely called hematogenous form. It is, moreover, proved that by ligation of the thoracic duct, as well as of the common bile-duct, no jaundice ever results, so that it is only through the lymphatics that the biliary elements can reach the blood.

Although the large part of the work devoted to a consideration of the physiology of gastric digestion leaves nothing to be desired, the author in his directions for practical laboratory-work in this line of importance to the clinician displays a lamentable ignorance of modern manipulative clinical and chemic methods, an ignorance so common with the English, who have so totally neglected the important field of applied gastric chemistry. Whatever may be said concerning the utility of a knowledge of the newer methods from a therapeutic standpoint, our debt to them as an aid in diagnosis is undoubted. Dr. Gamgee does not question either, and it is for this reason the more surprising that his book does not show evidence of his having done some practical work in this field so ripe for research. His description of methods for clinical laboratory-work in the body of the book are antiquated in the extreme, both in the mode of examination of the stomach-contents and that for obtaining the same. If the barbarous and antique aspirating method for the latter, illustrated on page 165, is popular in England, as one is led to suppose, there is slight wonder that a feeling there exists against the employment of the stomach-tube save as a *dernier ressort.* As curious a method is illustrated for lavage on page 166, and in his description of Ewald's trial-meal he speaks of a *well-buttered* (!) roll.

In a consideration of gastric digestion in special diseases Dr. Gamgee clings to the old English method of symptomatic nomenclature, and minutely describes a *flatulent*, an *acid*, and an *atonic dyspepsia*, as if they were special morbid entities, wholly separated from acute and chronic gastric catarrh, ulcer, atrophy, and carcinoma of the stomach, all separately noted. No mention is made of the neuroses of the stomach. These forms of dyspepsia, from the symptomatology cited, should clearly fall into some groups of these diseases. He is not up to date in these matters, as other unquoted passages plainly show. In the appendix Dr. Gamgee partly atones for the deficiency in one of these particulars. Here, in a few pages, the data for which he draws from the recent work of Martius and Lüttke, he gives in epitome an account of more approved methods of procedure in the examination of the stomach-contents.

Apart from the weakness in these particulars, the work is a splendid achievement, and will long live, with its sister volume, as an enduring monument to the fame of the distinguished author.

DISEASES OF THE EAR. A Text-book for Practitioners and Students of Medicine. By EDWARD BRADFORD DENCH, Ph. B., M.D., Professor of Diseases of the Ear in the Bellevue Hospital Medical College, etc. Pp. 645. New York: D. Appleton & Co., 1894.

THIS is a very handsome book, but it is too big. There are some glaring defects in the anatomic illustrations, though most of them are excellent. Why are two ossicles represented as lying loose in the tympanic cavity, as in Figs. 5, 3? This is grossly misleading to the beginner. Plates I, II, III, and IV, of the vascular and nervous supply of the middle and internal ears, are especially good.

The pages on physical examination of the ear are, for the most part, good; but we are surprised to find the position of the light shifted from the surgeon's right to his left, as on page 87. His left arm would thus be likely to get between the light and the mirror. Catheterization of the Eustachian tube is marred by the introduction of the old, impracticable, and septic catheters of Noyes and Pomeroy, and also by the suggestion to cocainize the nose before using the catheter. This is wholly unnecessary if the operator understands how to catheterize the Eustachian tube. If he does, he will not hurt the patient. Force should never be exerted, either with or without anesthesia.

Local abstraction of blood and incisions do no good in furunculosis of the ear. As they provide new furrows for the growth of septic germs, they do positive harm. So in acute otitis media, local abstraction of blood never aborts the inflammation; if dry heat will not relieve the congestion and pain, paracentesis is the only means of relief to pain and escape of the exudation.

Under middle-ear operations the author avails himself largely of the experience of other American aurists, even using their terms, like "stapedectomy" (Blake and Jack), without mentioning their names. He is the youngest worker among many older ones, in this field, in this country; but from his text one might justly infer that he is the only one. Buck and J. O. Green, who have labored for twenty years in mastoid surgery, are not even mentioned in this connection. Surely this young author should not withhold what is due these observers.

A Manual of Diseases of the Ear for the Use of Students and Practitioners of Medicine. By Albert H. Buck, M.D., Clinical Professor of Diseases of the Ear, College of Physicians and Surgeons; Columbia College, New York; Consulting Aural Surgeon, New York Eye and Ear Infirmary, and the Presbyterian Hospital. Second revised edition. One volume, post octavo, 467 pages, illustrated, with blank memoranda pages at the back. New York: William Wood & Co., 1895.

This book is commendably compact and of very reasonable price. It sets forth the general consensus of opinion as to the treatment of ear-diseases down to within about ten years, since which time our knowledge of bacteriology has gradually modified the views of many aurists concerning the treatment of ear-diseases, especially of acute otitis media. In this malady, if dry heat, or in some cases, if the mechanical pressure upon the membrana can be endured, warm instillations of carbolic-acid water (1.50 per cent. to 2 per cent.), cannot abort the process and ease the pain in five or six hours, spontaneous rupture must not be awaited, but paracentesis of the drum-membrane performed. Immediately upon the appearance of a discharge, either after paracentesis or a spontaneous rupture of the membrana tympani, the ear should be drained by placing in the auditory canal a narrow strip of iodoform-gauze or carbolic-acid-gauze, the meatus gently stopped with a little iodoform-cotton, and the ear let alone for twelve hours, or even longer, if the discharge is not copious. It is a mistake to syringe the ear, to drop anything into it, or to inflate the tympanum as soon as an ear begins to run, for fear of secondary infection of the middle ear. Drainage of exudation by way of the auditory canal is rather to be favored, for thereby the pathogenic organisms are carried from the middle ear. If the original acute otitis media is properly treated, no mastoid complications can ensue. The mastoid cavity has the ability to empty itself syphonically through the auditory canal, as it does probably in every case of acute otitis media in which the escape of the exudation is not impeded and in which no secondary infection is artificially set up.

The chapter on "Analysis of Symptoms" is a new one and of value to the general practitioner. The author is at home in the chapter on mastoid disease and operations. He rejects all intra-tympanic operations in chronic catarrh of the middle ear, but regards them as indicated to some extent in chronic purulent otitis media. But the ideal book, of not more than 300 pages, for "students and practitioners of medicine," has yet to be written. There are few things these busy men can learn of otology, and still fewer they can do for diseased ears. They could be told, however, that little, and also what to avoid even attempting to do, in much fewer words than this book, most valuable to a specialist, contains.

Text-book of Nervous Diseases, Being a Compendium for the Use of Students and Practitioners of Medicine. By Charles L. Dana, M.D. Third edition. With 210 illustrations. New York: William Wood & Co., 1894.

A work that has gone through three editions has received the stamp of professional approval, and any criticism thereon must be in the way of suggestion for further improvement rather than a judgment adverse to the merit of the work. Dr. Dana's style of writing is clear, and if he is somewhat more dogmatic than the present certainties of science justify, it is a fault to be excused in a teacher, and, perhaps, rendered necessary by the great condensation to which he has submitted the complex and difficult subjects of which he treats.

We are pleased to note that the author gives his adherence to that theory of exophthalmic goiter which regards the disease as an ataxia, or, to use the author's own language, a neurasthenic condition of the vasomotor centers and the visceral nerves. The attention which he devotes to hydrotherapy and his just estimate of the value of electricity are useful features of the book. The author speaks favorably, perhaps more so than the facts quite warrant, of the use of extracts of brain and nervous tissues in treatment. We must record our emphatic disapproval of the proposition to use tuberculin in the diagnosis of tuberculous meningitis. Some of the illustrations are useful; others are either so poorly executed or so overcrowded as to be rather more confusing than helpful. On the whole, however, the book is the best compendious work upon its subject in the English language of which we have knowledge, and we can once more commend it to our readers.

SYLLABUS OF LECTURES ON HUMAN EMBRYOLOGY: AN INTRODUCTION TO THE STUDY OF OBSTETRICS AND GYNECOLOGY. FOR MEDICAL STUDENTS AND PRACTITIONERS. WITH A GLOSSARY OF EMBRYOLOGICAL TERMS. By WALTER PORTER MANTON, M.D., Professor of Clinical Gynecology and Lecturer on Obstetrics in the Detroit College of Medicine; Fellow of the Royal Microscopical Society, of the British Zoological Society, of the American Microscopical Society, etc. Illustrated with seventy outline drawings and photo-engravings. 12mo, cloth, 126 pages, interleaved. Philadelphia: The F. A. Davis Co., 1895.

IN the preparation of this syllabus Dr. Manton has drawn not only upon the last editions of all of the standard works upon comparative and human anatomy, embryology, physiology, and obstetrics, but he has also consulted the recent current medical literature upon the subject, including the *Journal of the Royal Microscopical Society, the Zeitschrift für Geburtshülfe und Gynäkologie*, and the *Archiv für Gynäkologie.* The diagrams and drawings are largely original and are taken in part from specimens in the author's private collection. The book is interleaved for additional note-taking, and is made to meet the student's needs. The material is concisely and accurately presented, and as a syllabus the book merits honorable mention, especially from an obstetric point of view.

CORRESPONDENCE.

AN UNUSUAL SKIN-DISEASE.

To the Editor of THE MEDICAL NEWS,

SIR: H. G. R., male, single, aged thirty years, was by occupation a contractor and builder. Eight years ago, after skating continuously for ten hours, dressed in tights, he became quite warm, and walked from the rink to his hotel, a distance of six squares, dressed in his thin, close-fitting attire. From this exposure he became very much chilled, and immediately afterward, while changing his clothing, he was seized with an intense itching or irritation of the skin. This irritation began on the legs and thighs, but gradually extended all over the body, except his feet and scalp, which have never itched. Since that time he has been variously and vigorously treated, often with no relief whatever; but during this time, since the disorder first made its appearance, he has been entirely relieved for a period of twelve months, though the trouble would eventually return, and with each recurrence the irritation would be as intense and general as in former attacks. Upon examination of the skin I find the condition one of desquamation; as he exhibits the affected parts, beneath, on the floor, it appears as though there had been a light coat of fine meal dusted. On close inspection of the skin around the roots of the hair is to be seen a small scarlet or delicate pinkish eruption about the hair-follicles; the intervening skin is cracked or fissured, and is soon cast off. The discolored points are about half as large as the head of an ordinary dressing-pin. The itching is irregular, more intense at times than others. Sometimes it is worse at night; at other times it annoys him more in the daytime, and is more intolerable during cool weather than warm, for he states that during the summer or warm weather when at work and perspiring he is but little annoyed till he cools off, when it begins again. He states that following the periods that he was free from it, each return would follow some exposure to cold air. Accompanying this irritation are attacks of cold, chilly sensations, beginning at or near the coccyx and gradually increasing in extent and severity to one or both lower extremities. He says that when the itching is worse on the legs he can often get relief or render it unnoticeable by crossing his legs, with the worst one on top, and engage it in a swinging motion. His appetite is good, also his digestion. He sleeps well also. Occasionally, however, he is prevented from sleeping for an hour or two after retiring. He has no bad or vicious habits, never drank intoxicants of any kind; smokes and chews tobacco but little, and never had a venereal disorder.

What is the nature of this disorder? I should like to hear from experts on skin-disorders or upon nervous affections, according as the case may be classified.

Most respectfully, A. B. BAIRD.

OKLAHOMA CITY, O. T.

DEATH FROM "BABY DROPS."

To the Editor of THE MEDICAL NEWS,

SIR: I was recently called to see a four-months old infant to which a fatal dose of "baby drops" was given about two hours before. The following are the facts in the case:

The mother was in the habit of administering daily the required amount of "Lemberger's Magnesia Infant Drops," manufactured at Lebanon, Pa. On the previous day she had drained the bottle. Her druggist was out of Lemberger's, and he therefore influenced her to take "Mrs. Winslow's Soothing Syrup." Of this the label-dose was given without the desired effect following. A few hours later she concluded to rinse the sediment from the Lemberger bottle; and accordingly gave the entire quantity to the infant. In a very short time, indeed before it could finish nursing, it was sound asleep.

Its peculiar respiration and the strange appearance of the eyes soon caused alarm. When I first saw it the pupils were contracted to the size of a pin-point, and the respirations were stertorous, irregular, and greatly reduced in number. The child could be aroused with great difficulty, after which it relapsed almost immediately into a deep stupor. It could not swallow. It had been healthy from birth.

In view of the fact that fully two hours had elapsed since the toxic dose was given I decided to resort to atropin hypodermically, faradic electricity to the diaphragm, and cold water to the face. In this way life was sustained for sixteen hours. After twelve hours the symptoms of narcosis became associated with those of increasing depression. Paralysis of the centers of respiration was almost complete. In the height of the effect the respirations were reduced to two or three per minute, the longest intervals being thirty and even forty seconds. I used tentatively small quantities of alcohol injected, but all to be finally disappointed. The infant died a victim to the inhuman practice of drugging well babies to sleep, a custom as vicious as it is common.

J. R. JOHNS.

DENVER, PA.

A METHOD OF TREATING ALCOHOLISM.

To the Editor of The Medical News,

Sir: In reply to the request contained in a recent number of The Medical News for formulæ antidotal to the craving for alcoholic liquors, I would say that the great physiologic antagonism between atropin and alcohol does not seem as generally understood as it might be. If very small doses (less than $\frac{1}{100}$ gr.) of atropin be administered hypodermically three or four times daily to a victim of the liquor-habit, it will produce a great distaste for alcoholic liquors in from one to five days. Whiskey will become repellant both as regards sight and odor, and will have a most intolerable taste—as one man expressed it, like turpentine or benzine. If, under these circumstances, drinking is still attempted, it produces nausea and vomiting, without the addition of apomorphin or any substance whatever to the liquor. The drinker will almost invariably be turned completely against liquors in less than five days.

If this plan of treatment is pursued for its strong psychic effect, and if at the same time gentian, hydrastis, cinchona, strychnin, or other stomachic and general tonic is administered, with what other incidental remedies may be needed, it will constitute a very successful treatment of the liquor-habit, and when systematically carried out for three or four weeks will be very lasting in its effects. This curious antagonism between atropin and alcoholic liquors is the basis of some of the notorious "gold-cures" of the present day, and is a fact that should be used to better advantage by the regular profession in its treatment of the drink-craze. It should contraindicate or lead to caution in the administration of alcoholic stimulants to any patient already under the influence of atropin, hyoscyamin, or other mydriatic drug. In such cases it is likely to cause a foul, coated tongue, nausea, vomiting, insomnia, delirium, and possibly insanity.

C. C. Carter.

243 East Long Street, Columbus, O.

ON THE EARLY RECOGNITION OF CARCINOMA OF THE STOMACH.

To the Editor of The Medical News,

Sir: May I ask that you will permit me to add a brief postscript to my paper of February 16th, "On the Early Recognition of Carcinoma of the Stomach," that I may record the result of the last examination of the stomach-contents in the case mentioned on page 171, in which, although continuous improvement under treatment had occurred, no return of free HCl in the stomach-contents was evident at the time the paper was written (January 16th). A recent examination, made one month later, under the same conditions (the gastric contents removed one-and-a-half hours after Boas' gruel breakfast) showed a decided change for the better, well indicating the steady improvement that is occurring. Amount withdrawn 60 c.c.; well-solved, bile-stained. Congo paper blued and sharp Günzburg's reaction (demonstrating now, for the first time, the presence of free HCl). Total acidity: 40; no lactic acid; free and bound HCl: 0.06 per cent. Examination for pepsin not made, that for lab-ferment showed decided presence.

As concerns the diagnostic value of the presence of lactic acid, perhaps I did not lay sufficient stress in my paper on the fact that in the rare cases of carcinoma in which free HCl persists, despite the neoplasm, it is not to be expected that lactic acid will be found, save, perhaps in traces, the latter depending upon the percentage of free HCl present. As regards the negative value of the test, as recorded in the case related, it can, of course, only be regarded of utility in those in which, with symptoms simulating malignant disease, there also exist delayed propulsion and persistent absence of free HCl.

Very truly yours,

D. D. Stewart.

2620 N. Fifth St., Philadelphia.

NEWS ITEMS.

A Private Hospital for Contagious Diseases in New York.—A wealthy lady has offered the Board of Health of New York $25,000 to aid in the establishment of a private hospital for the treatment of contagious diseases, on condition that the money shall be used for no other purpose, that no part of it shall be applied to the improvement of any existing institution, and that the management shall be in the hands of the Board of Health and of a board of trustees appointed by the subscribers to the fund raised for the erection of the hospital.

Extra-mural Instruction in Medicine at Harvard.—The Faculty of the Medical Department of Harvard University has authorized approved physicians having the necessary facilities and desiring to teach its medical students to announce their courses in the Medical School.

The Sale of Patent Medicines in New York.—A bill has been introduced into the New York State Legislature giving the Board of Health the power to regulate the sale of patent medicines.

Dr. A. L. Benedict, of Buffalo, has been awarded the Merritt H. Cash prize of $100, by the Medical Society of New York, for an essay entitled "Auscultatory Percussion and Allied Methods of Physical Diagnosis."

Dr. John Whitaker Hulke, President of the Royal College of Surgeons of England and Senior Sugeon to Middlesex Hospital, died on February 19th, at the age of sixty-five years.

Four Years' Course at the Yale Medical School.—The Faculty of the Medical Department of Yale University has decided to extend the course of study from three to four years.

Dujardin-Beaumetz, the distinguished French therapeutist and clinician, died on February 15th, at Nice, at the age of sixty-one years.

Dr. Roswell Park, of Buffalo, was recently elected President of the Medical Society of the State of New York.

WRONG REFERENCE OF SENSATIONS OF PAIN.

BY S. WEIR MITCHELL, M.D.,
OF PHILADELPHIA.

It occasionally happens that in the large clinical material seen at the Orthopedic Hospital we meet with cases that are hardly capable of nosologic classification, and yet are not without their lessons. Here, as an example, is a case so unusual that rarely have I seen one like it or even analogous to it. It is a very simple story:

T. M. was sent first to my clinic at the Infirmary for Nervous Diseases by Dr. J. H. McKee, on December 7, 1894. She was sixty-two years of age, born in Pennsylvania, and married. Her mother died at the age of ninety-five, and her father at seventy-three from "cancer." Two sisters and three brothers are well. One sister died of "florid tuberculosis" and one brother of "spotted fever." The woman has borne three sons; two are well, and one is asthmatic. She takes two cups of strong tea and two of strong coffee daily, and beer moderately. The menopause occurred between forty and forty-five years of age. She has had pneumonia twice, once at fifty-two and again at fifty-seven years of age.

On November 25, 1894, thirteen days ago, while blacking a stove, she let a heavy stove plate fall on the *right* foot, striking the toes. The great toe and the adjacent one were injured, and were discolored from the bruising. A line of blackish discoloration is still present under the nail of the second toe. But there is no swelling or redness, though some pain still persists.

Immediately on the reception of the injury she felt acute pain on the antero-internal aspect of the left leg (the uninjured side) at the junction of the upper and middle thirds. This pain extended downward into the foot and upward into the thigh. It was of a burning character, fairly constant, but worse at night. At present the appetite is good and improving, the tongue is clean, there is no vomiting, but the woman has an occasional headache attended with nausea.

The heart's action is rhythmic, the sounds distinct. The vascular tension is moderately increased. The radial and temporal arteries are tortuous and resistant. There is slight vertigo, no dyspnea, and no swelling of the feet. There is an increased frequency of micturition, both nocturnal and diurnal. The urine contains no albumin or sugar and has a specific gravity of 1022.

The woman has lost flesh in the last two weeks. She has not had chills, fever, or sweats. She sleeps poorly and worse since the accident. Memory is good and hearing is fairly good, but the eyesight is poor, although improved by glasses. The station is a little unsteady. The knee-jerks are active, and sensation is apparently normal. There is no history of traumatism of the left leg. But the left tibia is now more sensitive than the right. It is particularly tender in the middle third, on the inner and outer margins. The left leg is also more florid and the temperature feels higher. There is no inflammatory or other deposit present. An electric examination of the tibial group of muscles shows a slight quantitative decrease to the faradic current. There is no galvanic change.

On December 21, 1894, the woman was better, and continuance of the electricity was ordered. On January 8, 1895, constant gain was reported.

I have personally gone over the case with extreme care, and see no cause to disbelieve the statement made by the patient. She declares that, having had a heavy weight fall on the right foot, there was at once a pain in the left shin, so sharp as to distract her attention from the quite severe injury received by the opposite member. Also she declares that the referred pain has now, for three weeks, survived that of the part hurt. The ache in the front of the left leg is becoming better since the use of galvanism and frictions.

This case, unusual as it is, seems not to be unique. In fact, I came yesterday, in Sharkey on *Epilepsy*, upon a case in which the pain caused by an injection for gonorrhea was felt as an acute pain on top of the head. A careful search through the books might enable us to find like instances. So far, however, Dr. Burr has not been fortunate in this search, probably because the cases are nowhere indexed as wrongly referred sensations. I myself recall two of which I have personal knowledge. One was that of a man who, having a felon on the right thumb, had, until it was relieved, severe pain in the opposite thumb. The reference thus was to both thumbs, and not from a foot to a non-symmetric part of the opposite limb. In another case, in which an omnibus-window was let fall on a finger on which was a felon, there was with the pain of the finger a brief but violent pain of the face and neck of the other side.

I have also some remembrance of having many times heard during the great Civil War, from men shot, statements as to their having felt the wound as pain in some remote part of the body. In the notes of that time made by Morehouse, W. W. Keen, or by me, I find, in fact, interesting examples of the kind of referred pain seen in this woman.

One was the case of Captain now Admiral Strembel, who, being shot through the right side of the neck, had with reflex paralysis of the left arm and also pain in that unwounded member. Other instances are as follows:

CASE II, of Circular No. VI, 1864.—A shell-wound of one leg (right) at once gave rise to burning pain in both feet and in the right arm and right pectoral region.

CASE IV.—A wound of the testicle was referred to the back, where alone was any pain felt.

CASE V.—A shell-wound of the outer side of the left thigh with immediate reference of pain to the same area on both thighs. The man thought, indeed, that he was shot through both thighs. Other of our cases exhibited similar phenomena of cross or symmetric or non-symmetric reference of the pain of a wound.

CASE IV, in Hutchinson's series, p. 313, is one of injury of the median and ulnar nerves which gave rise to pain in the opposite hand. Pirogoff has a report of the same form of cross-reference from a wound. Such false reports as to the seat of a pain-cause are not rare as regards the branches of a single nerve. A familiar example is seen or felt in the widely referred pain from an exposed dental nerve.

Our present case does not stand alone. Nevertheless, instances of cross-reference are rare enough to make it worth while to call them to your attention. This woman's case serves to remind me of other facts of like nature, but by no means identical.

One of my older friends, now dead, a naturalist of great distinction, had on one leg a small mole. If this was roughly rubbed or pinched, he had at once a sharp pain in his chin. More interesting are the cases in which after a nerve-section, or late in a neuritis, there is a reference centrad of a touch at some lower point. I long ago described this class of facts, and not very successfully commented upon their cause. In a book on remote histories of nerve-lesions, by John K. Mitchell, now in press, there are many illustrations of this form of referred touch-sense. He has also still more curious cases of sensations referred peripherad or to a remote region.

The unusualness of the present case lies in the continuance of pain in the remote region long after the seat of the originating cause had ceased to be painful.

I do not think that we are as yet prepared to reason upon some of these symptoms. As to what is to be said or has been, I refer the curious to the book I have just now mentioned. One can, in a measure, comprehend that a violent stimulus to a sensory nerve may be switched off on to other nerve-tracts or centers, as if it were the escape of an over-charge; but, even if we hazard such an hypothesis, it is still difficult to explain the persistency of certain of these transferred impressions, for it is a law of the receiving centers for painful impressions that when the cause of the pain ceases to be active the feeling of being hurt ends. But in some of these examples of false reference of pain there must have been made in a center some more or less permanent change that continuously represents the effect to which any pain-making agency usually gives rise.

THE EFFECTS OF TOBACCO-SMOKING IN MODERATION AS PREVENTIVE OF PULMONARY DISEASE.

BY CHARLES J. MONTGOMERY, B.S., M.D.,
OF AUGUSTA, GA.

EVERY now and then an article appears in a popular magazine or newspaper setting forth the evils resulting from the use of tobacco. As this indiscriminate condemnation of a luxury enjoyed by thousands has little or no effect, it is not often that anyone takes the trouble to say a word in its favor. That the excessive use of tobacco produces at times grave results no one will deny. This is also true of the excessive consumption of certain ordinarily wholesome articles of diet, and is especially true of many valuable medicines. But that these articles of food and these medicines should for that reason be condemned as altogether without virtue would indeed be unreasonable, yet no more so than to condemn the smoking of an occasional cigar, if it can be shown that this is not only not injurious, but in certain cases actually beneficial.

It is not my purpose to present indisputable proof that smoking is at times beneficial, but merely to offer a few suggestive thoughts and to present reasons tending to show the high degree of probability of benefit, especially in relation to certain pulmonary affections. Unfortunately this proof must remain to be demonstrated by future observers in the field of experimental therapeutics and bacteriology, for as yet too few experiments and observations have been made on this subject to enable one to speak with any degree of certainty. After a careful study of the literature on the subject of tobacco I find that there is but little known of the action of its smoke, it being apparently assumed that when we are told the physiologic effects of tobacco or its alkaloid, nicotin, when taken into the stomach and circulation of a man or lower animal we should be satisfied. Considering the fact, however, that one who smokes tobacco takes but a trace of nicotin into his stomach, while the smoke is filling his mouth and entering his lungs, it seems but reasonable to presume that the effects produced, whether for good or evil, are dependent almost wholly on the effects of the smoke.

For fear of misapprehension, I will here state that of those who smoke cigars and pipes there are but very few in whom the smoke drawn into the mouth is directly inhaled except in very small amount, but it chiefly enters the lungs subsequently on account of the air of the room being heavily laden with smoke. The majority of cigaret-smokers, however, usually inhale the smoke directly into the lungs before blowing it out of the mouth. Tobacco-smoke contains only the smallest trace of nicotin, but does hold several volatile bodies, mainly pyridin, picolin, lutidin, and collidin, which are said to have "somewhat the same action as nicotin, but less severe." It also contains hydrocyanic acid, hydrogen sulphid, phenol, and creosote. Phenol and creosote are invaluable in medicine for their antiseptic and bactericidal properties, and seem in certain conditions to exert a most beneficial action when applied locally. Hydrogen sulphid was at one time extensively used in the treatment of pulmonary troubles, and while this treatment is now rarely, if ever, employed, it is possible that by inhalation it might be of some small degree of benefit, especially when combined with more active substances. With regard to hydrocyanic acid, its calmative action on the lungs is well known. Tobacco itself has for a long time been used as a parasiticide, and the late Professor Formad, of the University of Pennsylvania, used to say that if the saliva of a man who did not use tobacco was injected into a rabbit the animal would die in convulsions, while the saliva of "smokers" had not nearly so toxic an effect. Is it not probable that this is so because the poisonous ptomains and bacteria which saliva ordinarily contains are rendered innocuous by constant contact with the smoke with its contained phenol, creosote, etc., and, if so, is it not likewise probable that this smoke when inhaled will kill or render inert microörganisms with which it may come in contact in the bronchial tubes, and in less degree in the lungs? And while we must probably allow that too small a quantity of the smoke as a rule enters the lungs to act in this manner, yet if the approaches to the citadel are protected the castle itself is secure. It is well known that certain chronic pulmonary diseases are largely due to the presence and activity of microbes.

I have thus referred to the subject from its antiseptic and bactericidal aspect. I will now say a word as to the physiologic effect of tobacco-smoke on the pulmonary circulation. As this effect is produced through the influence of the nerves, I first mention a few anatomic and physiologic facts prefatory to treating the subject from a physiologic standpoint. The nerves that supply the lungs are derived from the anterior and posterior pulmonary plexuses, which are formed mainly by the pneumogastric and sympathetic nerves, and for our present purpose we may only consider the pneumogastric, which is what is called a mixed nerve, *i. e.*, one supplying to certain regions motor influence, sensory, vasomotor, etc. This nerve is not only distributed to the lungs, but is the inhibitory nerve of the heart, preventing its too rapid action, and when stimulated, causing it to beat more slowly. Some of its branches are distributed to the larynx, pharynx, etc., not to mention other distribution, which does not concern us in this article. Now, the stimulation of an afferent nerve will, as a rule, increase the tonic influence of the vasomotor center, and through reflex action will cause a considerable constriction of certain arterioles and consequent local anemia. Now, it is more than probable that when the terminations of the pneumogastric and other nerves connected with it which terminate in the mouth, pharynx, etc., are stimulated there will be produced by reflex action a constriction of the pulmonary arterioles and capillaries. In tobacco-smoke we have an agent that at first stimulates the peripheral terminations of the pneumogastric. (When used to excess it is later a depressant of that nerve, but we are speaking of its use in moderation.) It also stimulates the peripheral terminations of the glosso-pharyngeal, the fifth, etc. The result of this stimulation of the pneumogastric is that by its reflex cardiac action the heart is slowed, while by its reflex vasomotor influence on the pulmonary circulation there is a constriction of the pulmonary arterioles and capillaries, and a mild degree of pulmonary anemia, or if there were previously a tendency to congestion, there would result an approach to a normal condition.

Now, as chronic pulmonary affections are largely dependent on chronic congestion, it is evident that a simple agent which tends to relieve or prevent this congestion is greatly to be desired. Here, then, is a condition in which a cigar is a blessing. The sedative action of tobacco-smoke on the lungs in cases of asthma, etc., is well known. How much of this is due to its hydrocyanic acid, how much to its creosote, its collidin, etc., or how much to the combined effects of all, is at present unknown; but the fact remains that it often affords relief. Perhaps it is partly due to its lessening local congestion in the bronchioles, as already described, as well as by allaying the spasm of their muscular coats. If, therefore, we have in the smoke of tobacco an agent that will destroy germs or prevent their development in the mouth, and to some extent in the bronchial tubes, and will relieve or prevent pulmonary congestion, is not this smoke a preventive of pulmonary disease? I may here add that even in those who smoke to great excess and inhale the smoke there is rarely, if ever, produced by it any direct injury to the lungs, unless it be due to certain extraneous causes, such as the paper covers of the cigarets being improperly made, and giving rise when burned to certain extremely irritating or poisonous substances being mixed with the tobacco-smoke, or, of course, by excessive smoking the general health might be so impaired and the vitality so lowered that the lungs, as well as other organs, would then be unable to resist disease. When care is taken that the covers for cigarets are properly made, as in France, where the Government regulates this, it is most probable that there rarely if ever would result any direct injurious effect on the lungs by the smoke of tobacco even in the form of cigarets and direct inhalation of the smoke. Though we must not forget the *reflex* effect of an *excessive* amount of smoke when the primary stimulation of the pneumogastric being followed by subsequent depression, there would result an increased frequency of heart-beats, dilatation of pulmonary arterioles, and consequent pulmonary congestion, which condition would be favorable to the development of disease.

It may be well, before concluding, to allude to the apparent protection against pulmonary disease which is afforded by working in tobacco-factories, though this is not universally acknowledged. In Stillé's *Therapeutics* we find it stated that "according to Dr. Rueff chronic pulmonary affections are infrequent among tobacco-workers, and he even affirms that some among them who enter the factory with emaciation, hemoptysis, and cough, have there got rid of their pulmonic symptoms." According to the same authority, in the tobacco-factories at Bordeaux, "consumption is unusual among the operatives, and the disease advances less rapidly in them than in patients placed under different circumstances." He further adds, "that in most of the tobacco-factories it is far less frequent than among the surrounding population, and indeed is in some quite unknown." Many others have made similar observations. So, while tobacco and its smoke have not received the scientific attention they deserve, enough is known about them to indicate it to be highly important that more careful study should be bestowed on these subjects, which are of such vital interest to humanity.

COSMIC DUST.

The Living Organisms Therein in Relation to Disease.

By THOS. S. BLAIR, M.D.,
OF HARRISBURG, PA.

An article I prepared upon this subject and published a couple of years ago has aroused so much interesting criticism that I have carefully investigated the subject anew, and venture to present it to the profession. At first sight it appears quite speculative, but I believe it warrants serious investigation.

That thousands of tons of meteoric matter and cosmic dust are annually precipitated upon the earth, and that the amount of such deposit is subject to great variation, are generally admitted. That much of this matter is permeated with life-germs has been announced by a few observers. Darwin described a shower of strange organisms covering an area of over a million square miles, proving by its extent an origin probably beyond the limits of our atmosphere. In a fall of yellow snow at Peckeloh, Germany, Weber found myriads of germs. A most remarkable cosmic shower occurred in 1755 in Northern Italy. The precipitation embraced an area of about two-hundred square leagues, and was an inch in depth at places, the Alps also being covered with a colored snow to the depth of nine feet. In October, 1846, a shower of microscopic organisms was observed in France, and over one-hundred different forms were described of a character similar to that of no known species. Ehrenberg estimated that forty-five tons of organic germs fell in this shower. In 1803 Italy and all Southern Europe were visited by a similar shower, and ten years later Calabria was the scene of a like phenomenon. Palestine and also Western Kentucky have had such showers. It is hardly reasonable to infer that the immense amount of organic matter in such showers is all of terrestrial origin. Recent investigations have proved colored snows to be filled with organisms, and the polar snows are said to have yielded more than three-hundred different life-forms. These organisms can hardly be produced in our atmosphere, millions of hundred-weight of them, according to Dana, having fallen since the days of Homer, who first described them in the *Iliad.* I have given but a partial list of such phenomena, and am indebted to Professor I. N. Vail for some of the data presented.

It is regarded as proved that all terrestrial matter, except as influenced by igneous action, contains living germs. Matter is matter throughout the universe, and it requires no stretch of imagination to believe that bacteria exist upon other planetary bodies and in the cosmic clouds in interplanetary space. It is quite probable our burned-out earth had remained sterile had no life-forms entered it in this manner, as life does not generate *de novo*. It is very reasonable to suppose that when "the primordial seas," geologists tell us, fell to the earth, they carried to it many forms of living matter, possibly in their present, but very much more likely in antecedent forms. We have seen that over three-hundred forms of life-germs, of presumably non-terrestrial character, have been discovered in cosmic-dust showers. From what we know of germs in general *some* of these forms must have pathogenic properties. Many, of course, are dead, others are myceliæ, and but a portion bacteria. Many of the latter are undoubtedly non-pathogenic. It is unfortunate that cultures of these germs have not been made and their properties tested; but granting that no single one among them is possessed of specific pathogenic influence, we know that their action, if present in great numbers, would be deleterious to higher animal life, because any species of bacteria existing in sufficient quantity has such qualities. Very fatal epidemics of intestinal and other disorders have resulted from the mere accumulation of filth in which bacteria rated as non-pathogenic abound.

Careful observation has shown that the amount of cosmic matter descending in occasional notable showers, great though it is, is but small compared to the constant imperceptible additions of such matter to the earth. Hence, if cosmic germs influence the health of higher animal life on the earth the factor is a constant one. Bacteria reaching us from an environment differing from that they find here might at once perish because of temperature-changes or lack of the necessary elements for their growth, and so be negative in their influence, and doubtless many forms are so. Countless myriads of the cosmic germs reaching us are dead, presumably because of the intense cold of space, but it is remarkable how tenacious of life are some germs and the spores of most bacteria. Certain varieties will thrive in ice. I have not the article at hand, but I remember reading detailed experiments made about 1889 that proved that the ordinary bacterium termo could, in successive generations of its growth, be gradually subjected to greater and greater heat until germs were made to thrive in a temperature fatal to their ancestors. Some of these germs might live for a time and then die out. If they did, any disease they might engender would die with them.

In the fourteenth century the so-called "Black Plague" *suddenly* came upon the world and carried off nearly fifty-million victims. It was apparently a specific germ-disease and spread much faster than the lines of commerce could carry it. It seemed to be everywhere, on sea and land. An old chronicle says: "The impure air was actually visible as it approached with its burden of death, and a dense and awful fog was seen in the heavens." On several occasions peculiar clouds have accompanied plagues. What caused the black plague, and why has it ceased from off the earth? That the earthquake and volcanic eruptions preceding it could be the cause will hardly stand scientific scrutiny, nor will the presence of filth and the lack of food account for a specific disease of uniform type throughout the known world. On the theory that the plague was caused by cosmic germs, these difficulties are removed, and its widespread character understood. Its cessation might be ascribed to the earth swinging out of range of the cosmic dust carrying the germs, which, not finding proper environment on the earth, ceased to multiply, and so became extinct. The old type of "spotted fever" could be accounted for on like grounds. It is almost unknown now, and much resembled the "black death" of 1866 and 1867, which is now an extinct disease. Between the years of 1811 and 1846 epidemic cerebro-spinal meningitis largely prevailed as a practically new form of disease, and was widely spread and very fatal. The epidemic form of this disease has all but disappeared. Here, then, we have a group of epidemic affections coming unannounced and as quickly disappearing. Demonstrated theories do not account for this.

In a second group might be placed diseases presumably caused by an influx of large numbers of previously unknown cosmic germs, finding a suitable habitat only in certain regions, and, after the *first advent* of the affection, *limiting* their influence to that portion. Yellow fever is a marked instance in point. First appearing at the end of the fifteenth century, it was widely diffused, but, probably when new accessions of the germs causing it ceased, the disease limited itself to regions where they found suitable soil. Be this the cause of the limitation of area amenable to the disease, or not, we know that at present yellow fever is limited to an area within 48° of the equator, and to no more than 2500 feet above sea-level. Dengue or "dandy fever" is of this group. Coming suddenly in 1827, it gave Philadelphia pathologists an opportunity to speculate upon "jimson weed" and other equally amusing etiologic factors. It is still attributed to many causes, but we know it soon died out except in southern latitudes, because it is probable the germ can only flourish there.

The large group of epidemic diseases, such as typhoid fever, diphtheria, and scarlet fever, are commonly designated "filth-diseases," and they will doubtless be held more and more in check as civilization advances along hygienic lines; but these epidemic manifestations not caused by filth have always been a puzzle to me. Our most recent plague, "la grippe," has prompted this investigation on my part. It also came suddenly. It prevailed throughout nearly the whole world, and, in a few weeks' time, was "quite the style." It came insidiously, as the latest popular song, and all manner of theories have been advanced as to its cause. Most of them attribute it to some peculiar quality of the atmosphere irrespective of prevailing winds and lines of travel. Sensible people readily enough admitted that electric currents or an excess of ozone was its cause, simply because such speculation is "the order of the day." I am well aware that the germ-theory of disease is being overdone, and that bacteria are supposed to cause nearly all ills except old age, poverty, and credulity; but, looking at the matter candidly and without conventional bias, it has appeared to me at least reasonable to attribute this disease to cosmic germs. The history of the affection thus far lends color to the view. Were I a prophet I would predict that every winter for a few years yet we will have more or less influenza, but that in ten years it will be practically extinct.

Finally, I may say that while the foregoing theory seems to me to be reasonable and explanatory of some scientific puzzles, it will require elaborate research at the hands of many investigators for its full establishment or for its entire overthrow.

PRELIMINARY NOTE UPON A FEW OF THE CHANGES FOUND IN THE FIELDS OF VISION WHILE THE EYES ARE PLACED AT RIGHT ANGLES TO THEIR ORDINARY POSITION.

By CHARLES A. OLIVER, A.M., M.D.,
ATTENDING SURGEON TO THE WILLS EYE HOSPITAL; OPHTHALMIC SURGEON TO THE PHILADELPHIA AND PRESBYTERIAN HOSPITALS, ETC.

In the fall of 1893, during a conversation with Dr. S. Weir Mitchell, of this city, he spoke to me of the advisability of conducting a series of scientific experiments in order to determine why it is that a more vivid color-impression of a distant landscape can be obtained when the head is bent down into a horizontal position. To perform these properly Dr. Mitchell suggested that a study of the relative values of both form and color-fields whilst the head is held in the ordinary upright position and whilst it is lowered into as near a horizontal one as possible, might be of use in determining the reason.

These experiments, which I performed with the aid of a number of assistants and friends, will be fully explained in a paper that, although finished some several months ago, is being reserved for later publication.

After duly considering the differences of color-values when reflected through the various meridians of the dioptric media and the increase of physiologic power from greater blood-supply to the organ when the head is held in the lowered position, the conclusions reached in this paper, after some two hundred or more experiments, show definitely that such a change in the position of the eye practically brings the most sentient portion of the retinal sheet into a situation that allows it to receive impressions from a part of a distant view that ordinarily impinge upon a lower grade of material, which gives a less vivid and a less detailed visual picture.

Dr. D. Hack Tuke, the well-known alienist and author, died in London on March 5th, at the age of sixty-eight.

CLINICAL MEMORANDA.

ASTHMA AND ANEMIA RELIEVED BY REMOVAL OF NASAL POLYPI.

By J. B. SCOTT, M.D.,
OF GETTYSBURG, PA.

Although it is well known that nasal affections cause asthma, it would appear from the history of this case that the fact is not generally given the recognition that its importance demands. I therefore report the case just as it happened, because it seems to constitute a strong plea for the more general examination of the nasal passages in diseases of the respiratory tract, and also of the circulation.

Five years ago, an elderly lady came to me for treatment for bronchitis, asthma, and a condition of general malnutrition. She was anemic; the pulse was irregular both in frequency and in power; there was no cardiac murmur. *The nasal passages were not examined.* The bronchitis and the general condition improved under treatment, but the asthma was uninfluenced. At the close of the summer she changed her residence, and during the five years past has resided in several of the cities of the Middle and Southern States. In each place she was treated by physicians of reputation, some of whom were eminent. The result was invariably the same, some improvement in the bronchitis and general health, but the asthma grew worse. *None of the physicians examined the nose.* Last summer she again came to me, and greeted me with the remark: "Doctor, I don't expect you to relieve the asthma; it seems no one can do that in all these years, but if you can only give me something to relieve the awful dryness in my mouth at night, so that I can get a little sleep, I will be grateful."

As there was no local disease of the mouth to account for the dryness, mouth-breathing due to nasal obstruction occurred to me as a possible explanation of the symptom, and an examination was made through the nasal speculum. The left nostril was seen to be literally packed full of mucous polypi, while in the right passage a big one, looking like an oyster, acted like a ball valve, alternately opening and closing the slight air-current that found room to pass. Here seemed to be the solution of the whole problem. Nasal respiration being impossible, the mouth necessarily remained open and became dry, while the inspired air, deprived of the warmth and moisture normally imparted by the nasal mucosa, irritated the bronchial tubes, and maintained the chronic inflammation. The feeble and irregular circulation was due to a reflex action on the heart.

The patient having been told that some benefit might result from removal of the polypi, readily assented to the operation. The polypi were attacked with a Bosworth's snare and Allen's forceps. I say "attacked," because it proved to be a right bloody battle before they were gotten out, but it ended in victory, for that night the patient was entirely free from asthma—a new experience to her. The next night, however, there was a slight return. Examination showed that a small polypus, which had pressed out from one of the recesses of the cavities, after the removal of the others, was obstructing the passages. It was removed, and with it disappeared the last vestige of the asthma. Three months have passed without any attack, while before they were of nightly occurrence.

Although a sharp exacerbation of the bronchitis resulted from exposure to cold, it was unattended with any asthmatic symptoms. It, therefore, seems clear that the asthma was due to the polypi, because it stopped on the removal of those obstructing the passage; it recurred when one hidden from view at first appeared in the left cavity, and because the exacerbation of the bronchitis was not attended by any asthmatic paroxysm. *The whole physical condition of the patient was improved*, probably as a result of the more perfect respiration, and consequently more perfect oxygenation of the blood. The varied experience of this patient seems to show that, even in certain high places, examination of the nasal passages is not a routine measure, and it certainly shows that it ought to be in diseases both of the respiratory tract and also of the circulatory system, particularly in *anemic* cases.

PAROXYSMAL HEMOGLOBINURIA DUE TO COLD.[1]

By LOUIS FAUGÈRES BISHOP, M.A., M.D.

My patient was a male, fifty-five years old, a native of Denmark, a sailor, whose father died of apoplexy and mother by accident. One brother died of pulmonary tuberculosis, one sister died of inflammation of the bowels, and two sisters are living. The man had smallpox in 1871, yellow fever in 1854, malarial fever in Savannah in 1860, but in all cases made good recoveries. About twelve years ago, after exposure to extreme cold for a long time, he passed blood-colored urine, with a stinging sensation along the urethra. Since then, whenever he is exposed so as to get his hands and feet cold, the blood-colored urine has reappeared. During the winter he has suffered severely on account of the severity of the weather. During warm weather he has never had an attack. During the past four weeks there have been ten or eleven attacks. When the attack comes on there is a very urgent desire to urinate, and urine is passed in spite of efforts to retain it. This happens as long as the urine is very dark, but when it becomes clearer the desire is not so urgent. He has had severe attacks of pain in the back for eight or nine years. When the urine contains blood-pigment the amount is diminished.

There are no signs of cystitis or of stricture. In summer, when he is free from the ordinary attacks, he is troubled with attacks of cerebral symptoms at night, during which he rises from sleep, frightened, and imagines that there is someone going to put him in a barrel, etc. He drinks bitters, and about five or six glasses of beer daily, occasionally a little whiskey. In 1859 he was exposed in a wreck, at which time a companion was frozen to death. He served in the army during the war, and was much exposed. He attributes his disease to exposure. He can produce an attack artificially at any time by voluntary exposure to cold. An examination of the urine between the attacks was negative; during the attacks a small amount of albumin was present, and it contained much blood-pigment, but very few blood-cells; there was a deposit of a very heavy brownish sediment. It seems very probable that this man's idea of the cause of his disease, namely, exposure, is the true one.

The recurrence of cerebral symptoms replacing the attacks of hemoglobinuria is curious. Dr. William Osler mentions a case in which epileptic seizures occured at the same time as attacks of hemoglobinuria; here we have cerebral symptoms occurring at the times when the attacks are absent. In this case there is nothing to suggest Raynaud's disease, which has frequently been associated with this condition. The sufferings of this man are great, and as there did not seem to be any way of influencing his condition by medication he was advised to take up a permanent residence in a warm climate, but it would be disastrous should the cerebral symptoms become more frequent in the absence of the attacks of hemoglobinuria.

36 West Thirty-fifth Street.

BACTERIOLOGIC REPORT.

A DETAILED REPORT OF SOME EXPERIMENTS IN THE PRODUCTION OF THE DIPHTHERIA-ANTITOXIN.[1]

(*From the Bacteriologic Laboratory of the Medical Department of the University of Wooster, Cleveland, Ohio.*)

By A. P. OHLMACHER, M.D.,
PROFESSOR OF PATHOLOGY AND BACTERIOLOGY.

This report has for its object the description of a series of experiments in the manufacture of the diphtheria-antitoxin, which, with the support of several of my colleagues,[2] have been recently completed. While I have in the main followed the directions of European authorities for the production of the antidotal diphtheric serum, my methods have varied in certain particulars from those prescribed. Aside from this, many technical difficulties have been encountered and overcome which are not clearly described by the authorities in this work, so that it is hoped this report will contain some valuable suggestions for others engaged in similar experiments.

The diphtheria-bacillus employed was isolated from a throat-swab sent to the laboratory by Dr. Charles Gentsch, of Cleveland, November 4, 1894. The patient from whom the swab was obtained was a girl, five years of age, who presented the clinical symptoms of a moderate attack of diphtheria. The false membrane partially covered each tonsil. The child recovered perfectly in four or five days. Four days before the illness of this child, her brother, aged six years, had died of diphtheria, which invaded his larynx.

The diphtheria-bacilli that appeared in the eighteen-hours' culture on Loeffler's medium were separated from the only other contaminating organism (*Diplococcus lanceolatus*) by the employment of scratch-attenuations on plates of Loeffler's medium. Morphologically, the isolated bacillus was found to be an extreme type of the long, irregular, beaded variety of the *Bacillus diphtheriæ*. In fact, in its early cultures this bacillus showed a tendency to form longer rods than I have ever seen in the diphtheria-organism. While this fact is emphasized, it is not my opinion that the length of a diphtheria-bacillus bears any constant relation to its virulence, as some observers contend; and I hope to show in a future communication that a very short bacillus may be found to possess even greater pathogenic properties than a long one. It fortunately happened, however, that this particular example of the Loeffler bacillus possessed very virulent properties, and that its virulence was retained to a remarkable degree.

---

[1] Read in abstract before the Cleveland Medical Society, February 22, 1895, and illustrated with specimens showing various stages of the work.

[2] I take this occasion of returning thanks to my friends who have, in various capacities, assisted me during these experiments.

Dr. H. W. Kitchen obtained the horse, and Dr. C. B. Parker kindly placed his stable at our disposal. Dr. I. J. Kerr assisted at most of the operations on the horse. Dr. Cooley aided us in locating the jugular vein at the first bleeding, and Mr. C. F. Nelson has been useful in many minor but essential capacities.

After isolating the bacillus in pure culture its virulence was tested by injecting 0.5 c.c. of a twenty-four-hours' bouillon-culture under the skin of the belly of a healthy guinea-pig weighing 350 grams. Precisely twenty-four hours after the injection the animal died, with the usual symptoms of diphtheria-intoxication preceding its death. An autopsy made fifteen minutes after the death of the animal revealed all the usual lesions of experimental diphtheria.

In the interval before commencing the manufacture of the toxins the isolated bacillus was tested by the usual cultural methods. It was found to grow typically in gelatin without liquefying the medium; to produce acids first and alkalies later, in glucose-litmus agar; to make "invisible" growths on potato; and to multiply in milk without coagulating it.

THE MANUFACTURE OF THE TOXINS was commenced November 18, 1894, when 250 c.c. of ordinary neutral beef-peptone-bouillon were inoculated from the sixth generation of our bacillus, which had been all the while grown on Loeffler's medium.

In the preparation of the first lot of toxins the method of Roux was partially followed. The bouillon was kept in a large Erlenmeyer flask, with a side-neck, both the mouth and the side-neck of which were stopped with cotton before the sterilization of the flask and its contents. The bouillon-culture was allowed to grow for twenty-four hours in the incubator, after which the side-neck of the flask was connected with a Chapman aspirator, and a current of the moist air from the incubating chamber was drawn over the top of the culture. The aspirating apparatus was disconnected at the end of one week, and the culture was kept in the incubator till November 30th. The purity of the bouillon was now tested by scratch-attenuations on plates of Loeffler's medium, and, as no foreign organisms were found, the bouillon was passed through a Kinyoun filter. To the clear, yellow, germ-free filtrate ½ per cent. of carbolic acid was added. This carbolized filtrate was our diphtheria-toxin, and it was kept at the ordinary laboratory-temperature until it had all been used.

The potency of this lot of toxin was tested according to the standard formula. With the aid of the long, graduated pipet of a Petri syringe, 0.1 c.c. of the toxin was injected under the skin of the abdomen of a lively guinea-pig weighing 400 grams. During the first twenty-four hours the animal showed no signs of illness. At the end of thirty-six hours it was decidedly sick, and presented the same symptoms of intoxication shown by the pig previously inoculated with the bouillon-culture of the living diphtheria-bacilli. The animal died between the fortieth and forty-eighth hours. The autopsy showed, in an exaggerated form, all the lesions noted in the pig killed with the bouillon-culture of the same bacillus.

After the completion of this first lot of toxin, more of the material was prepared. In all of the later products I have done away with the troublesome methods of attempting to "force" the cultures by currents of air or oxygen. In fact, in my own work I have departed, in certain particulars, both from the French and German formulæ. The French method, proposed by Roux, consists in forcing the bouillon-cultures with currents of moist air, with the employment of a formidable battery of special flasks; and the culture is grown for a month, when it is filtered with bacteriologic precautions to prevent contamination, no disinfectant being added to the filtered toxins. This method takes too long; the elaborate apparatus is expensive, and, I believe, useless; and the finished toxins are liable to become infected unless the most rigid precautions are taken in handling them.

The Germans grow their bouillon-cultures for two or three weeks in ordinary flasks, then add carbolic acid or trikresol, and employ this mixture, containing the dead bodies of the bacilli. This method has the merit of simplicity, but I cannot convince myself that the injection of the immense masses of dead diphtheria-bacilli[1] is desirable, to say the least. I have, therefore, adopted an intermediate method of making my later toxins.

Ordinary sterile, neutral, beef-peptone-bouillon (about 800 or 900 c.c.), contained in a common liter bacteriologic flask, is inoculated and set in the incubator. Once a day the flask is agitated, to distribute the bacilli that tend to settle to the bottom of the flask. It will be noticed that, like bouillon-cultures of other bacteria, the diphtheria-bacilli grow diffusely in the bouillon for the first few days, and then settle to the bottom of the medium. At the end of two or three weeks in the incubator the bacilli will be found to have entirely subsided to the bottom, and the overlying bouillon will be comparatively clear. The bouillon-culture is now tested for contaminating organisms, and, if found to be pure, ½ per cent. of trikresol is added, with agitation to secure its solution. After standing an hour or two the bouillon is filtered through any one of the unglazed porcelain filters employed by bacteriologists. The resulting brilliant, pale-yellow fluid containing ½ per cent. of trikresol is the finished product. It contains no bacteria, and, in virtue of the trikersol,[2] no bacteria can develop in it, even though it be kept in an ordinary stoppered bottle and handled without special precautions. These toxins may be kept at the ordinary room-temperature, and while it may be preferable to keep them in the dark, I have not observed any diminution of virulence in a lot of the toxins kept in the light of the laboratory for several weeks.

---

[1] At this point I may remark that I can see absolutely no excuse for the employment of the very dangerous methods in which the *living* diphtheria-bacilli are used to secure immunity in the horse. We know altogether too little about the ultimate relation of the living bacilli to their host; and from experiments on smaller animals it would not be surprising to find that the horse will ultimately succumb to a chronic diphtheric cachexia after inoculation with the living bacilli. These objections are especially significant, it seems to me, as we can secure an equally powerful immunity by a much less dangerous method.

[2] Trikresol is employed in preference to carbolic acid because it is claimed that is not so toxic for animals, and that it is a more

A liter of toxins from the eighth generation of our diphtheria-bacillus was finished January 14, 1895. During its stay in the incubator this culture was exposed to some hardships, for, owing to the extremely cold weather, and to an imperfect gas-regulator, the temperature of the incubator varied, on several occasions falling to 30° C., and several times rising to 40° C.

This lot of toxins was tested on January 15, 1895, by injecting 0.1 c.c. into a guinea-pig weighing 390 grams. Twenty-four hours after this injection the animal was very sick. Between the thirtieth and thirty-sixth hours it died, with the usual symptoms.

This lot of toxins has been used for the immunizing injections in the horse from January 15th to February 12th, and it has been kept in an ordinary glass bottle at the laboratory-temperature all of the time. Although it has been tested several times, it has never failed to kill a guinea-pig inside of thirty-six hours in an injection of 0.1 c.c., showing it to be a more powerful product than the first lot made from an earlier culture with the aid of the "forcing" method.

As these toxins are all that could be desired for potency, I conclude that a little fluctuation in the incubating temperature is not harmful, and that the efforts to increase the intensity of the toxins by growing the cultures at a higher temperature than that ordinarily maintained in our incubators are useless. In fact, I may here remark that my experience only strengthens my conviction that the whole secret of intensely virulent toxins lies in the employment of a variety of the diphtheria-bacillus that happens to possess a high grade of virulence when it is implanted into the bouillon. I do not believe it possible to intensify the virulence of its toxin-production by artificial means once the bacillus has gained access to the culture-medium. Undoubtedly such factors as the composition and reaction of the bouillon culture-medium have considerable influence in determining the character of the toxins manufactured by the bacilli, but these factors are quite as much beyond our control (in their finer relations), and are as much matters of chance, as is the virulence of a given variety of the diphtheria-bacillus. Our bacteriologic technique is not above scientific reproach, and the last word on the question of variation in bacteria has by no means been spoken.

It has only been in the last lot of toxins, from the ninth generation of our bacillus which was obtained three months ago from the patient, that a diminution of virulence has been observed. In order to attempt the restoration of the lost virulence I shall resort to a method that I have recently found very effective in some other experiments with the diphtheria-bacillus, and that differs in one respect from the usual method. I shall inject a half a cubic centimeter of a twenty-four hours' bouillon culture of the bacillus under the skin of the abdomen of a guinea-pig. As soon as the animal has died a bacteriologic autopsy will be made, and instead of recovering the diphtheria-bacilli from the local focus of infection, as is ordinarily done,[1] pieces of the liver, spleen, or adrenals will be transplanted to bouillon; and after two or three days tubes of Loeffler's medium will be inoculated from these bouillon-tubes, when the bacilli will be recovered, and if they are found to have acquired increased pathogenic property they will be employed in making a stronger lot of toxins. This prediction is made with due conservatism, however, for my increasing acquaintance with the inexplicable variations of the diphtheria-bacillus has tended to diminish my feeling of security in any particular experimental method.

As to the Production of Immunity in the Horse. On December 20, 1894, a horse was procured for the continuation of our experiments by my colleague, Dr. H. W. Kitchen. The animal, a mare, nine years of age, and weighing about twelve hundred pounds, was sound physically, though it showed the evidence of poor care, and was unfit for road use on account of the bad condition of the forelegs. The animal had simply been worn out, so far as its travelling capacities were concerned, by overwork on the stone-paved streets of this city. Since the mare has been under the excellent care provided for her in Dr. Parker's stable she has improved wonderfully in flesh and spirits, notwithstanding the fact that she has been exposed to a gradual intoxication with the diphtheria poison.

The spots chosen for the injections were over the shoulders. An area of skin about six inches in diameter was clipped and shaved, and before each injection it was disinfected. The smaller injections were made in a single dose; the larger quantities of toxin were injected in two lots divided between the two sides. The smaller injections were made with a Koch syringe, and the larger ones were made with a small aspirating syringe, with a cut-off arrangement, by which the syringe could be filled from a bottle and the fluid then forced into the tissues of the animal.

The first injection of the original toxin was made on December 20, 1894, the day the animal arrived at its new quarters. Precisely 0.5 c.c. of the undiluted toxin was injected with a Petri syringe. The following morning the animal refused its mess of oats, and it gave an exhibition of bad temper for two or three days following

---

powerful germicide. The question of a non-toxic germicide is of some importance, as in the large doses (250 c.c. or more) of toxins injected into the horse considerable of the germicide is administered.

[1] Bardach (Annales de l'Institut Pasteur, Tome ix, No. 1, 1895, pp. 40–55) has just recorded some very interesting though very much prolonged experiments in the intensification of the virulence of an old diphtheria-culture. Arguing that the diphtheria-bacilli that survived the phagocytosis at the point of inoculation possessed more hardy characters than those that succumbed, he proceeded by injecting bouillon-cultures under the skin of a dog, and, after fifteen hours, recovering the bacilli from the local exudate. In this way the virulence was slowly reinforced, but it was only after *twenty-five* such passages through the dog that a high grade of virulence was established in the bacilli. In my own work I have not attempted to recover the bacilli from the seat of inoculation, but believing that those bacilli which gained access to and survived in the visceral organs were the most virulent, I have recovered them from these organs. In this way I was able, for instance, by a single passage through a guinea-pig, to make a diphtheria-bacillus that only killed a guinea-pig in fourteen days become so virulent that it killed an animal of equal weight in thirty hours, in a much smaller dose.

the injection. This was all the constitutional disturbance that could be discovered, and there was no marked elevation of pulse or temperature. Locally, however, the effects of the toxin were very marked. Within three or four hours after the injection an area of 3 or 4 cm. in diameter became swollen. This swelling increased and became indurated during the following five days, when it gradually subsided. Three days after the injection a series of blisters appeared over the swollen spot at the site of injection, and after the blisters subsided the superficial layers of the skin raised by these vesicles exfoliated. No other evidences of necrosis were discovered. This injection gave the most pronounced local reaction that we have observed.

A week following the first injection 1 c.c. of the toxin was administered. Then these quantities were injected: January 2, 1895, 2 c.c.; January 7th, 5 c.c.; January 11th, 10 c.c; January 15th, 15 c.c. (new toxin); January 19th, 30 c.c.; January 23d, 60 c.c.; January 28th, 100 c.c.; February 1st, 180 c.c.; February 5th, 250 c.c.

Thus the advance from 0.5 c.c. to 250 c.c. was made in one month and sixteen days, and but eleven injections were required to complete the immunity. The first five injections were from the original lot of toxin, which killed a guinea-pig in from forty to forty-eight hours in a dose of 0.1 c.c. The remainder of the injections were made with the more simply prepared lot of toxin, which killed guinea-pigs in from thirty to thirty-six hours in a dose of 0.1 c.c.

The effects of these injections in the horse were both local and general. Locally, the tumor that was induced by the injection of the mass of liquid under the skin persisted two or three days, and the spot felt hot and appeared to be painful when pressed upon. The injections were all made in the afternoon, and the horse usually refused its evening mess of oats, and for the first few hours after the injection of the poison stood with drooping head and ears and the dejected look of a sick animal. Usually it brightened and ate and drank well the day after a dose had been administered, though it always exhibited bad temper for a day or two after the injection, so that the attendant sometimes had trouble in entering the boxstall in which it was kept. This bad temper, which was especially directed against myself, precluded the possibility of systematically taking the animal's temperature; though there was no striking elevation of temperature or increase of pulse on the occasions when these observations were made. Twice the reactions to the toxin were unusually sharp. After the injection of 10 c.c. the local reaction was more pronounced than ordinary, the swelling was more marked and seemed more "feverish" and tender than usual. After the injection of 60 c.c. the animal appeared to be decidedly sick for two or three days. It stood perfectly still and refused its food and drink for two days. This injection was, by mistake, made deeper than usual, and I have no doubt the toxin found its way along the muscular fasciæ, as the usual local tumor of a subcutaneous injection was not apparent after this dose. Instead of this, a diffuse swelling developed and extended from the shoulder down the corresponding leg, as though the poison had infiltrated along the muscular sheaths, causing an inflammatory reaction wherever it touched. The animal seemed to suffer principally from a lameness of the right shoulder and foreleg over which the injection was made. The trouble was aggravated, I am sure, by the previously poor condition of the forelegs. As no such reaction was ever observed after any of the injections made simply under the skin, I have concluded that deep injections are objectionable, and that they will seriously delay the progress of immunity. On the whole, however, the animal's tolerance of the poison was remarkable, and, by watching the effects carefully, and pushing ahead fearlessly, the desired end was reached in a very short time and without serious mishap.

Since the maximum dose of 250 c.c. was given, the horse has received two injections. On February 12th, 150 c.c. were given, and on February 18th, 250 c.c. I shall now inject about 150 c.c. of the toxin once a week between the bleedings, and give a dose of 250 c.c. four days before a bleeding.

BLEEDING THE HORSE. On February 9th, four days after the administration of the dose of 250 c.c. of the toxins, the horse was bled for the first time. Some swelling still marked the site of the injection-tumor, but the animal was in excellent constitutional condition. At this first operation 400 c.c. of blood were obtained for purely experimental purposes.

The method of bleeding that I have adopted also varies from the directions usually given. A considerable area of skin over the location of the operation-seat is clipped and then shaved. A thorough scrubbing with green soap and water succeeds; and then the skin is disinfected by copious washing with a corrosive-sublimate solution, followed by alcohol and ether. The jugular vein is located by securing its distention with the finger of an assistant pressing upon the vein low down in the neck, then an incision is made in the direction of the vein, about midway between the head and shoulders. A careful dissection is made so as to expose the vein for an inch or two of its course. By occasionally provoking the distention of the vessel it can be more easily located in the depths of the wound. The vessel is now loosened from its surroundings and carefully drawn out of the wound with a strong, long-handled, blunt hook.[1] When everything is ready the vessel is clipped with a pair of scissors, and the flowing blood is caught in the receptacle provided. By properly manipulating the blunt hook under the vessel, the stream of blood can be guided in any desired direction; and by simply making a little traction on the hook, the flow of blood can at once be stopped. When sufficient blood has been withdrawn, a deep suture of silk is inserted so as to bring the edges of the muscles together *over* the vein; the vessel is then released, the suture tightened, and in a few moments the bleeding will all cease. Then the superficial wound is to be closed with a few silk sutures, and an antiseptic gauze dressing is applied. Of course, this operation must be performed with proper surgical precautions; and a gauze compress must always be at hand to clap over the vein in case of accident, to prevent the inspiration of air and air-embolism.

At the first bleeding some careless exploration with the unclean fingers of an untrained assistant gave us an infected wound, and a smart cellulitis with local suppuration was provoked. The second operation was performed with only a slight reaction at the site of operation.

---

[1] I have employed for this purpose an ordinary uterine sound, bent at a proper angle.

Compared with other methods of bleeding I think this procedure has some advantages. It is less troublesome than the bleeding through a canula, and the stream of blood can be guided, and the bleeding stopped, quite as readily as with the more complicated method.[1]

The first 400 c.c. of blood were caught in a 16-ounce, wide-mouthed screw-cap jar.[1] At the second bleeding, made February 21st, about 3000 c.c. of blood were caught in seven of these 16-ounce jars. The jars were first disinfected by washing with sublimate, alcohol and ether, and then drying in a hot-air oven.

AS TO THE SEPARATION AND PRESERVATION OF THE SERUM.[1] As soon as the jarful of blood is caught, the cover is replaced, and it is set aside, undisturbed, until the whole mass of blood has firmly coagulated. This takes from one-quarter to one-half an hour. The "buffy coat," characteristic of slow coagulation in horse's blood, often appears, and this must not be mistaken for serum. As soon as the blood has firmly clotted it is transported to the laboratory. A clean spatula-blade is now carefully passed between the clot and the sides of the jar so as thoroughly to loosen the clot from top to bottom. Then the blood is set aside in a cool place. The next day a considerable quantity of clear, straw-colored serum will be found on the top and at the sides of the contracting clot. This serum must be carefully drawn off with a large (25 c.c. or 50 c.c.) pipet, and transferred to a clean vessel. During the removal of the serum the blood must not be agitated or else red blood-corpuscles will rise and spoil the serum, though they may be partially removed by the use of the centrifugal machine. On the second, third, and even on the fourth days additional quantities of good serum can be obtained from the blood, providing it is kept cool and sweet. So long as the serum remains clear, straw-colored (not red), and sweet, it is available. This serum is our *diphtheria-antitoxin*.

We now come to a matter that, while very small at first sight, is nevertheless of much importance; that is, the preservation of the serum. To read the ordinary directions for this procedure one gets the idea that all that is necessary is to add ½ per cent. of carbolic acid or ⅓ per cent. of trikresol to the serum, and its preservation is assured. "Das ausgeschiedene klare Serum wird abgeschöpft, mit 0.5 per cent. Carbol versetzt, um es haltbar zu machen und das Diphterieheilmittel ist fertig." But the desired end is not so easily reached.

The importance of proper preservation was forcibly impressed upon me recently, for I found a sample of a certain commercial antitoxic serum to be literally swarming with a variety of bacteria after a few days' stay in my laboratory.

No better culture-medium for pathogenic bacteria can be desired than this blood-serum, and, unless proper care is taken, the serum becomes the culture-ground for myriads of bacteria, almost before we are aware of a change in its character. Of course, it is possible, by the exercise of extraordinary precautions, such as filtering with bacteriologic precautions, to obtain a sterile serum which may be kept in sterilized vessels until it is wanted for clinical purposes. But even with the most rigid care it is rarely possible to obtain a germ-free serum, and, even were this possible, the serum could only be placed in the hands of a trained bacteriologist for clinical purposes. We must, then, abandon the idea of employing sterile blood-serum for practical purposes, and add to the serum some chemic substance that will safely preserve it, even when it is handled with the ordinary precautions of a physician.

The question of a suitable chemic preservative for the serum is not a matter of indifference. The agent should be (*a*) odorless; (*b*) nontoxic, even when injected in considerable doses; and (*c*) without deleterious influence on the antidotal proteid contained in the serum. The substance should be odorless, so that it will not disguise even the faintest trace of a putrefactive odor, which must at present remain our best rough test of the serum's freshness.[1] In the preparation to which I have alluded camphor was employed as a preservative, and when the fluid was first examined no trace of a putrefactive odor could be detected. It was only after the serum had been shaken vigorously that an odor like that of decayed oysters asserted itself over the odor of the camphor, although the serum was swarming with bacteria. The objection to carbolic acid and trikresol is that they may produce poisonous symptoms of their own when injected in the considerable quantities called for in large doses of the serum. Further, when these substances are added directly to the serum they precipitate some of the proteids. Used in aqueous solutions sufficient to raise the proportion of these chemicals to ⅓ or ½ per cent. a considerable dilution of the serum would be necessary.

In some preliminary experiments made with ordinary serum I encountered all of these obstacles. Besides carbolic acid and trikresol, I tried formalin, chloroform, thymol, boric acid, salicylic acid, and sodium salicylate. Formalin, even in dilute solution, preserves the serum from decomposition, but it causes the serum to become gelatinous; and then we know little about the effects of subcutaneous injection of this substance into animals. Chloroform preserves the serum well as long as it does not volatilize, but it is irritating in injections. Thymol dissolves too feebly to be useful. Boric acid does not possess sufficiently vigorous antiseptic powers. Salicylic acid, in solution with borax, was found to preserve the serum well, though it is a difficult substance to dissolve without the use of water, and water dilutes the serum. Of all the substances I have tried, I have decided upon sodium salicylate as the most eligible for the purpose. It is odorless, and its powder dissolves readily in the serum without producing a precipitate or cloudiness. Its influence in injections, in the quantities required, appears to be perfectly harmless, and we are well acquainted with the therapeutic effects of the drug. It preserves the serum well, as I have found by some very severe tests, such as keeping the serum to which it had been added in an ordinary unsterilized flask for several weeks in the air of a warm laboratory. At the end of this time the serum was perfectly clear and odorless, and a drop examined with the microscope showed no living (motile) organisms. Moreover, this substance in no way interferes with the antitoxic properties of the serum.

---

[1] No argument is necessary to emphasize its advantage over the method in vogue with veterinarians, in which they plunge a knife (usually dirty) deeply into the tissues of the neck, stab about until the vein is hit, and then attempt to urge the flow of blood by pressing on the vein below the cut, and by occasionally digging the knife into the wound. The blood flows everywhere except where it is wanted, trickles through the hair of the animal's neck, and stops flowing every few moments. Then the wound is closed with a couple of dirty pins, and a figure-of-8 suture of hair taken from the horse's tail completes the toilet.

[2] These jars, made by Whitall, Tatum & Co., of Philadelphia, are very well suited to the collection of blood for these purposes. They are of very convenient size and shape, and as they have no shoulders it is possible to obtain easy access to the clotted blood.

[3] I desire to emphasize the great importance of employing small vessels for collecting the blood from which the serum is to be obtained. From a considerable experience in the collection of serum from cow's blood, and from one previous experiment with horse's blood, I was never able to obtain more than from 500 to 700 c.c. of available serum from 4000 c.c. of blood, when this blood was all caught in a single large jar. At the first bleeding, however, I used a small jar, and I was surprised to find that from 400 c.c. of blood I was able to obtain 200 c.c. of good serum. Acting on this suggestion I used seven small vessels to catch the 3000 c.c. of blood of the second bleeding, and from this quantity of blood I have obtained 1700 c.c. of perfectly clear, straw-colored serum. When we remember the precious quality of this product, any method that will yield an increased quantity is of much value. I believe the advantage of this method of collection lies in the fact that the contraction of the clot can be more effective in a small mass of blood than when it is exerted on a single large mass.

[1] Camphor is used by Roux, and trikresol or chloroform by the Germans. All these workers filter the serum through unglazed porcelain.

For the present, then, until some better substance can be recommended, I shall employ sodium salicylate as a preservative for the antitoxin. For this purpose I add 1 per cent. of the dry powder directly to the serum, and allow it to dissolve.

Even with the best of preservatives I think it highly desirable, however, to keep the serum in an ice-box until it is to be dispensed; and I would advise the physician who uses any of the products upon the market to follow religiously the direction, "keep in a cool place." As to the necessity of keeping the serum in the dark, I have, as yet, had no experience from which to speak.

TESTING THE ANTITOXIN. On February 10th the salicylated serum obtained from the first lot of blood was treated for its antidotal properties as follows:

Three large guinea-pigs, Nos. 1, 2, and 3, were each given an injection of 1 c.c. of the diphtheria-toxin, mixed with the horse's serum. The toxins here employed were of the same lot as had been injected into the horse, and two days before the test was made 0.1 c.c. of these toxins killed a 300 gram guinea-pig between the twenty-fourth and thirty-sixth hours. This tenfold fatal dose of the toxin was mixed with the antitoxin in such proportion that Pig No. 1, weighing 530 grams, received 1 c.c. of toxin and 0.5 c.c. of antitoxin. Pig No. 2, weighing 590 grams, was given 1 c.c. of the toxin and 0.25 c.c. of the serum; while Pig No. 3, weighing 625 grams, was injected with 1 c.c. of toxin and 0.1 c.c. of antitoxin. The proportions of toxin to antitoxin used in these animals were 10 to 5, 10 to 2½, and 10 to 1.

Not a trace of either local or constitutional reaction has been observed in any of these little animals. Now, eighteen days after the injections, they are all alive and well, their temperatures are normal, their nutrition is good, and not one of them shows a trace of the diphtheric cachexia that often supervenes as a late manifestation of diphtheric intoxication. As these animals have each survived ten times the usual fatal dose of a very virulent diphtheria-poison, we can only conclude that their lives have been spared and illness prevented by the antidotal influence of the horse's serum, even when employed in the proportion of one to ten. For the preliminary tests of the diphtheria-antitoxin these results are remarkably good, and they show that while our methods differed in some details from the usual ones, and while our injections of the toxins into the horse were pushed more rapidly than ordinary, the resulting immunity and the production of a powerful antitoxin were none the less perfect.

In order to complete the testing of the serum according to the European formulæ, it will be necessary to find the smallest possible amount of the serum that will protect a guinea-pig against a given amount of the toxins. According to Behring's notation, the value of a serum is expressed by the proportions that a certain dose of the toxins and a certain quantity of the antitoxin bear to the weight of the experiment-animal, the antitoxin being injected twelve hours before the toxins. Ehrlich's standard is obtained by taking as a unit one cubic centimeter of a serum that in a dose of one-tenth of a cubic centimeter will neutralize ten times the usual fatal dose of the toxins when mixed with it and injected into the animal. By neutralization is meant the complete nullification of the toxins, so that they will produce neither local nor constitutional effects. Guinea-pigs are the animals employed for these purposes.

I have not yet standardized my serum according to these formulæ. In the first place, I do not know the precise fatal minimal dose of my toxins, though I am sure it is considerably under 0.1 c.c. This test and any further tests have been suspended on account of a failure in our supply of guinea-pigs.

In reviewing the essential points in the production of the diphtheria-antitoxin let me lay stress upon:

1. The necessity of obtaining a pure culture of a highly virulent diphtheria-bacillus.

2. The fact that the toxins may be made by simply growing the bouillon-cultures of the diphtheria-bacilli in the incubator for two or three weeks, then adding ½ per cent. of trikresol, and filtering.

3. The secret of a highly potent toxin lying in the virulent characters of the organism employed.

4. The fact that the immunizing injections in the horse can be pushed more rapidly than is usually done.

5. The fact that a number of small vesselfuls of blood will yield more serum than a single large vesselful.

6. The advantages of sodium salicylate as a preservative agent for the diphtheria-antitoxin.[1]

---

[1] These experiments were made solely for scientific purposes, and the antitoxin is not for sale. The comparatively small quantity that we can produce will be used by us in those local cases in which a bacteriologic examination can be made. The data obtained from the use of this product on patients will ultimately be used as the basis of a clinical sequel to this report.

MEDICAL PROGRESS.

Trephining for the Relief of Hemorrhage from the Cavernous Sinus Due to Fracture of the Skull.—WATSON (*Boston Medical and Surgical Journal*, vol. cxxxii, No. 4, p. 78) has reported the case of a lad, nineteen years old, who was struck on the head by a brick thrown from a height of twenty feet. He fell, but immediately rose again, falling on his knees, however, an instant afterward. He then got up and walked across the street, and complained of pain in the right eye and above it. Consciousness was lost after an hour, and did not return until the following morning, although the patient could be roused so as to make motions with the limbs. The left pupil was dilated and did not react; the right pupil was normal. Both extremities of the right side were paretic. The knee-jerks were normal; the paralysis steadily increased, and the loss of consciousness gradually became more profound. A slight, simple depressed fracture could be felt an inch to the left of the median line, just anterior to the coronal suture. A large semicircular incision was made, and a skin-flap reflected. Hemorrhage was prevented by transfixing the base of the flap with a needle previous to the incision and compressing the base with a piece of tape passed around it and drawn tightly on the shaft of the needle. The skull was trephined over the site of fracture, and a large blood-clot found beneath the opening. The fracture extended in two radiating lines toward the base of the skull, anteriorly to the outer angle of the orbit and laterally downward toward the petrous portion of the temporal bone. On removing the clot profuse hemorrhage took place. A channel half an inch wide was rapidly cut through the bone along the anterior line of fracture toward the outer angle of the orbit, and enlarged at its lower end. A large blood-clot was then seen to occupy the whole temporal region, and to extend forward and backward beneath the base of the brain. On removing the clot the respiration, which had become slow, shallow, and irregular, at once resumed its normal character. The finger could now be swept over the orbital plate, and the line of fracture could be clearly felt] extending diagonally across it to the sella turcica. From this point arose a profuse hemorrhage, which, so far as could be determined, originated at the point of junction of the ophthalmic vein and the cavernous sinus. The bleeding from this place was controlled by firm packing with iodoform-gauze. The posterior radiation of the fracture could also be clearly followed from the depression on the vertex well down toward the petrous portion of the temporal bone. From this region also a brisk hemorrhage was taking place, probably from a branch of the middle meningeal artery. This was likewise controlled by firm pressure with iodoform-gauze. The ends of the gauze were led through the lower end of the opening into the skull and through a counter-opening in the base of the skin-flap, the edges of which were united with silk sutures. The packing was not removed until the tenth day. The patient made a rapid and uninterrupted recovery. On the morning following the operation he was perfectly intelligent, and complained of no pain or other symptoms. In twenty-four days he was out of bed, and on the twenty-eighth day he was dismissed, well.

Gastro-enterostomy with Bone Plates for Pyloric Obstruction.—SINCLAIR (*British Medical Journal*, No. 1778, p. 188) has reported the case of a man, forty-three years old, who had been a dyspeptic for twenty years, and presented frequent gastric pain, relieved by vomiting. The site of pain was some three or four inches from the pylorus, but a pyloric tumor could not be made out. Weakness and emaciation increased, and the signs of dilatation of the stomach developed rapidly. Treatment was futile, and the washing out of the stomach with a syphon-tube afforded most relief. The man steadily lost strength, flesh, and color, and finally an operation was determined upon in the belief that cicatrization of an ulcer was responsible for the dilatation. On opening the abdomen, gastro-enterostomy was selected in preference to pyloroplasty, on account of the hard, cartilaginous feeling of the pylorus, and decalcified bone plates were employed. The visceral wounds were made very ample, and the plate sutures were supplemented by a row of Lembert's sutures. The stomach was incised about two-and-one-half inches from the greater curvature, and about seven inches from the pylorus. The jejunum was opened about one foot from the duodeno-jejunal junction. The intestine was doubled back upon itself before applying it to the stomach, in order to secure correspondence in the direction of the peristaltic waves in the two organs. The subsequent course of the case was uneventful. For three days nothing by the mouth was permitted, but four nutrient injections were administered daily. On the third day tea, wine, and water, and meat-juice were allowed by the mouth. By the fifth day soup, beef-tea, and white foods, and on the eighth day fish and fowl were added. On the twelfth day ordinary solid food was permitted. The patient got out of bed on the fifteenth day, and two weeks later was ready to resume his duties as a railway-engineer.

Acute Yellow Atrophy of the Liver in a Child Two Years Old.—DONKIN (*Lancet*, No. 3723, p. 28) has reported the case of a girl, two years old, who presented well-marked discoloration of the skin and conjunctivæ. It was stated that three weeks previously she had suffered with cough, constipation, sleepiness, and failure of appetite. Jaundice had been noticed for two weeks. The stools were white, and the urine deeply colored. There had also been vomiting and restlessness at night. The child appeared to be seriously ill. The liver was found to extend one finger's breadth below the costal margin, and appeared somewhat hard and smooth. The upper limit of dulness was perhaps a little lowered. No other abnormality could be detected. In the course of twenty-four hours the restlessness increased, and loss of consciousness supervened, being followed in turn by maniacal delirium. The pupils were equal and rather contracted, but reacted to light. The pulse was 120, and regular; the temperature normal. The jaundice increased in intensity, and the child became very thirsty. Petechiæ appeared on the front of the legs. Later in the day the child became quieter and drowsy, and the pupils dilated and sluggish. The temperature rose to 100° and the pulse to 140. During the night coma gradually set in. Petechiæ became more numerous and the jaundice more intense, and on the following morning the child vomited a quantity of blood and died shortly afterward.

Although a post-mortem examination could not be secured, and there was no opportunity of examining the urine for leucin and tyrosin, the diagnosis of acute yellow atrophy of the liver was thought to be amply justified.

Rhythmic Cough of Nasal Origin.—JOUROUKSCHI (*La Médecine Moderne*, 1894, No. 101, p. 1583) has reported the case of a woman who came under observation on account of persistent cough, which had been present for five-and-a-half years. At first occurring at considerable intervals, the attacks gradually recurred with greater and greater frequency, every four or five minutes, and causing great fatigue. The cough somewhat resembled the barking of a dog. In the absence of a discoverable lesion a diagnosis of hysteria was made, but despite all treatment improvement was not effected. The patient coming under observation a second time, a tumor, which proved to be a lymphadenoma, $\frac{3}{4}$ inch long and $\frac{4}{10}$ inch thick, was discovered in the naso-pharyngeal space in contact with the vomer. On removal of the neoplasm the cough permanently disappeared.

THERAPEUTIC NOTES.

The Treatment of Diphtheria with the Antitoxin.—RANKE (*Münchener medicinische Wochenschrift*, 1895, No. 8, p. 157) reports the employment of the antitoxin in the treatment of one-hundred-and-two cases of diphtheria, twenty-one having died, seventy-four recovered, and seven being at the time yet under treatment. Two of the cases were complicated by measles and eight by scarlatina, and among these there were five deaths. Of the eighty-five uncomplicated cases in which a definite result was known, there were sixteen deaths (18 per cent.). Of this number, bacteriologic examination was made in sixty-five, with positive results in sixty-four. Of the eighty-five cases of primary diphtheria, fifty-four (63 per cent.) presented on admission symptoms of laryngeal stenosis. In seventeen of these fifty-four cases the symptoms subsided after the injection of the antitoxin. In the remaining thirty-seven intubation was necessary.

The mortality from diphtheria in previous years ranged as follows: 1887, 42.2 per cent.; 1888, 43.9 per cent.; 1889, 46.5 per cent.; 1890, 47.9 per cent.; 1891, 46 per cent.; 1892, 56.2 per cent.; 1893, 46 per cent.; and in 1894, prior to the use of the antitoxic serum, 57 per cent.

HECKEL (*Ibid.*, p. 159) has reported six cases of diphtheria treated with the antitoxin, in four of which peptonuria was observed.

Radical Cure for Chronic Dysentery of Recurrent Type.—At the recent Indian Medical Congress GALLAY (*British Medical Journal*, No. 1779, p. 276) related eight cases of chronic dysentery of recurrent type to illustrate the curative effects of large enemata of a solution of crystallized silver nitrate in distilled water, a scruple to a quart. The patient is placed on his right side with the left thigh bent; an enema of tepid water is given first, and when this has acted the solution of silver nitrate, to which from 20 to 30 drops of laudanum have been added, is thrown up. The patient tries to retain it for a few minutes, two, three, or five minutes being the maximum; sometimes it is evacuated in two efforts, the second evacuation being separated from the first by a few hours' interval. The only immediate ordinary consequence of the washing is a sensation of stricture at the lower part of the rectum, which passes away after a quarter of an hour at most. Often from the first washing the amelioration is complete, but at any rate it can be relied upon to follow the third or fourth washing. To secure, however, permanent relief, it is necessary to continue the treatment, and a course of sixty washings is recommended.

Salipyrin for Metrorrhagia.—ORTHMANN (*Berliner klinische Wochenschrift*, 1895, No 7, p. 145) has employed salipyrin in the treatment of fifty cases presenting metrorrhagia from various causes. The drug was given in the form of pastilles, each containing fifteen grains, and one of which was taken thrice daily. When possible, the administration was begun a day or two before the anticipated hemorrhage, and continued through the entire course of bleeding. The total amount given in individual cases varied between three-hundred grains and two-and-a-half ounces. In no case were unpleasant results noted. Forty-five of the cases were under observation for from three-quarters of a year to a year-and-a-half, and from thirty-two exact personal reports were obtained and final examinations made. In twelve of these no satisfactory result at all was obtained. In twelve there was distinct improvement, and in the remaining eight the result could be designated good. The best results obtained were in cases of metrorrhagia following labor or abortion.

The Chlorin quinin Solution of J. Burney Yeo, for the treatment of typhoid fever, referred to in an article by Dr. Emil King in THE NEWS of March 2d, is made as follows: Thirty grains of powdered potassic chlorate are put in a twelve-ounce bottle and sixty minims of strong hydrochloric acid added. A greenish-yellow gas is at once liberated. The bottle is well-stopped and its contents agitated until the bottle is filled with gas. Then water is added, little by little, closing the bottle and shaking it well at each addition, until the bottle is filled.

In twelve ounces of this solution from twenty-four to thirty-six grains of quinin are dissolved, and syrup of orange-peel is added to give an agreeable flavor. The dose is an ounce every two, three, or four hours, according to the severity of the case.

The Sero-therapy of Tuberculosis.—At a recent meeting of the St. Louis Medical Society PAQUIN (*Medical Review*, 1895, No. 8, p. 147) reported a number of cases of tuberculosis treated by injections of blood-serum of horses rendered immune to the disease. The method of preparation was withheld. The serum was administered in does of from ten to one-hundred-and-fifty drops once daily. Among fifteen-hundred injections but two abscesses formed.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM, IN ADVANCE $4.00
SINGLE COPIES 10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM . . . 7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MARCH 16, 1895.

"ATHLETICS."

THERE has been found one medical journal to espouse the cause of what is passing nowadays under the name of athletics, and we are implored to consider the logic brought forth by a professorial contributor. We have examined the argument as presented by PROFESSOR RICHARDS in the March number of the *Yale Medical Review*, and find it exactly like all previous arguments in favor of foot-ball. It is just as guilty of unwarrantable assumptions of premises, of inconsequential conclusions, just as cunning in ignoring and misstating, just as biased and one-sided as have been all the previous pleas. It is exactly like the argument of a cheap lawyer bound to free his client at all costs. Every old hack statement brought out to bolster up the ruined cause has been repeatedly knocked into smithereens, except, perhaps, that remarkable one about the rise of cities and the growth of athletics, and every telling fact against the author's cause is ignored or minimized. There is nothing more damnatory of the foot-ball craze than such disingenuous arguments and such illogical fustian by supposed logicians. The shrewder men, like Brer Rabbit, recognize that it is better to "lay low and say nuffin," hoping that the storm will "blow over." We are glad to believe that both the silently sly and the schoolboyishly logical are each equally poor judges of public opinion. The public is quite as likely to follow the leading of President ELIOT as of the professor who stigmatizes him as no longer "able to look at more than one side of the subject." We therefore trust that the defenders of foot-ball will continue their defences. Every attempt is an added nail in the coffin of their cause.

We turn with the greatest relief and pleasure from such tricksiness to the straight-out ingenuousness of a blabber of the whole secret. In *The Peterson Magazine* for March, 1895, there is an article that, like an *enfant terrible*, blurts out the whole truth, without sentimental nonsense, moral whine, or patriotic jingoism. DR. ADAMS, in speaking of the progress lately shown by a great Eastern college, says:

> The victories of our foot-ball team in the past few years have undoubtedly been worth more to the institution than an endowment fund of $1,000,000. This may seem at first thought an extravagant statement, but let us stop to consider it. The interest on $1,000,000 is $50,000 a year. This is balanced by the various elements set to work by the enthusiasm created by these victories. In the first place, on the purely financial side, the increased interest in athletics for the past few years has resulted in the building of a $100,000 athletic field. But it has done far more than this: it has paved the way to a more brilliant future for the university; it has attracted the attention and admiration of thousands of growing boys in whose hands to a certain extent is left the choosing of their college for future study. This means that hundreds of boys who might have gone to Harvard, Yale, or Princeton, and whose brothers did go, are now seriously debating the question of remaining in Philadelphia to complete their education. It may seem hard lines that a great educational institution must depend on its success in athletic fields for a proportion of its students, but such is the case, and the college authorities have long since wakened to the truth. It is due to the fact that the American student is generally able to persuade his parents to send him to the college of his choice.
>
> Again, the interest of the public is aroused in the institution by these recent successes, and, having it in their minds, many persons charitably disposed are far more likely to remember it pecuniarily. Then it has hastened the growth of the "university spirit," as will be spoken of more at length later in this article. Again, the fame of the university has spread to many circles and to many regions where it was hitherto but little known. Its affairs attract as much attention now as do the matters concerning the other great universities, a national interest in its affairs having been established. These various influences, aroused or stimulated recently, are worth far

more to the university than $50,000 a year, for they mean growth and activity for increased efforts. This is encouraging, etc.

This refreshing and frank truthfulness, however, suggests many inquiries, among them the following:

1. For what were universities of learning founded?

2. Is it any great advantage to the community or to learning to have students drawn from one college to another?

3. Is the boy the best judge of what constitutes the best institution of learning, and of what are the best educational methods?

4. What about the dignity of advertising an institution of learning by semi-professional "athletic" shows?

5. What will be done with the students stolen from other colleges when they are secured?

6. If foot-ball is far and away the saver of the race, why prepare but a single $100,000 athletic field? Several thousand students will require hundreds of such fields in order to permit all students to acquire the "intellect,"[1] the "morality," the "obedience,"[2] and the muscle requisite in life, and, according to foot-ball logicians, obtainable only by means of foot-ball.

7. Is the "university spirit" so glorious when it results in such a bitter rivalry as to-day exists between Princeton and Pennsylvania, and when it forces one of these colleges to demand a truce of hostilities for a year, in order, *as it is said*, to let the boys "cool off"?

Just as the greatest crimes against religion and freedom are committed in the name of religion and freedom, so the greatest crimes against education are those by professional educators, and also, we may add, the greatest crimes against athletics are perpetrated in the name of athletics. In a certain sense the medical profession is the guardian of the health of the community. It, therefore, becomes the duty of every medical man to protest against the abomination of the proprietors of university shows carrying on their business of college-advertising in the name of physiology and hygiene. There is plainly creeping through the popular mind a sneerful suspicion of the very word athletics. It is a poor booby that cannot see that, *e. g.*, golf, or base-ball, has every advantage claimed for foot-ball, and is without almost every one of its disadvantages. The name athletics is becoming scorned, and by the subtle law that governs the changes in the meanings of words is being changed into a term of reproach. With the debauchery of the thing there quickly follows the contempt of the word, and genuine athletics will, by reaction and revulsion, become detested, just as the contemptibleness of the dispensary-abuse is preparing a sentiment that will end in the starvation of legitimate medical charities.

Nowhere is this manifest more plainly than in the rise and luxuriant growth of pugilism and of "athletic" clubs. All over the land in every city there are many, sometimes with one or more thousands of members. In almost every town of any size there is at least one so-called athletic club, the attractions of which consist of almost nightly prize-fights, euphoniously called glove-contests, sparring or boxing matches, not of the members, but of hired professionals. These two subvarieties of athletics, prize-fighting and foot-ball, give nine-tenths of the popular interest in "athletics," and in a little while the word will connote these things principally or alone.

What we wish to make clear is that neither sparring nor foot-balling, as at present carried on, can be legitimately called athletics—and simply because the spectators who are as one-hundred or as one-thousand to one, indulge in no athletics except the laryngologic type. They sit (or stand) and watch the hired men do the athletics. It would be as true to call a theater full of people a school of dramatic art for the spectators. One may see acting or athletic contests all one's life and never become an actor or an athlete.

When we get educators who care either for education or for genuine athletics we shall have something quite different from the present intercollegiate advertising-show variety. Then will physical exercise be subordinated to mental exercise, brawn to brain, and athletics to erudition; then ALL of the students will be encouraged to develop the body in rational and non-injurious ways. We shall then not be witnesses of the disgrace of professional educators egging on the mob of non-athletic thousands to cheer the dozen or two of the show team put in conflict to advertise their college, and to attract students and endowments.

---

[1] The famous Yale "Lit." prize was not awarded this year because not one of the essays handed in was deemed worthy of any recognition.

[2] The *New York Herald* of February 24th contains a column-long account of the attempt of the students of Princeton, "among whom were several members of the University foot-ball team," to break up an entertainment of the townsmen given in Odd Fellows' Hall. A fight followed "with beer-bottles, baseball-bats, and fence-pickets, as well as fists;" the "students" were finally whipped. In the same issue of the *Herald* is an account of "a lively battle" at the Bloomington (Indiana) College in which "'Sophs' were taken from their beds and tied to trees, and a student's skull fractured." These things happened about the day Professor Richards was writing that foot-ball had stopped the old practice of hazing.

THE TREATMENT OF EXTRA-DURAL HEMORRHAGE BY TEMPORARY RESECTION OF THE SKULL.

CURRENT medical literature teems with reports of successful intracranial surgery, and abstracts from a considerable number of important operations have recently found place in the Progress department of THE MEDICAL NEWS. As we have already taken occasion to say—in part directly, and in part by implication—the surgery of the brain and the brain-case differs only from the surgery of other parts of the body in the anatomic and topographic relations of the structures, in conjunction with the difficulties of diagnosis. The application of this generalization—in fact, its very promulgation—is but one of many advances made possible by antiseptic and aseptic surgery. When the diagnosis is reasonably clear the surgeon now has almost as little hesitancy in opening the skull for the evacuation of a purulent accumulation, the removal of a neoplasm, or the control of hemorrhage, as if any of these occurred in less vital or deep-seated parts, and the success of such intervention has fully justified the boldness of the undertaking. With growing operative skill, improved technique, increased precision in diagnosis, and maturer surgical judgment, many lives must in future be saved and much suffering averted by a timely application of the principles evolved out of a fuller and riper experience in the treatment of intracranial diseases.

In a recent communication WAGNER (*Berliner klinische Wochenschrift*, 1895, No. 7, p. 137) directs renewed attention to a mode of operating on the calvarium for the relief of intracranial conditions described by him a number of years ago under the designation of temporary resection of the skull, and since by others as osteoplastic resection or trephining, and reports two cases of hemorrhage between the dura and the bone in which the procedure was successfuly carried out, the hemorrhage controlled, and recovery ensued. In both a fracture at the base of the skull ensued from indirect violence, and a hematoma of the dura mater formed in the middle fossa, resulting in the one from a laceration of both branches of the middle meningeal artery and in the other from a laceration of the anterior branch and of the transverse sinus. The diagnosis was arrived at from the presence of typical symptoms of progressive pressure upon the brain, preceded by a characteristic so-called free interval, separating the stage of concussion, without hemorrhage, from that of the actual extravasation of blood.

In the stage of shock the pulse is usually small and frequent, but with the increase in brain-pressure it becomes slow, harder, more tense, and often irregular. As a rule, paralysis of the opposite side of the body appears, indicating that the extravasation is beginning to exert pressure upon the motor area. Convulsions are of frequent occurrence, and may be ascribed to anemia of the medulla oblongata.

The only remedial measure under these conditions is the evacuation of the extravasated blood and the control of further hemorrhage. This should be undertaken as soon as symptoms of pressure make their appearance, as manifested by somnolence and paralysis. In the absence of definite knowledge as to the source of hemorrhage it is perhaps best to remove a flap of bone from the skull in the angle formed by the intersection of a line passing horizontally two-fingers' breadth above the malar bone by another passing vertically a thumb's breadth behind the ascending process of the same bone. Should the bleeding not be accessible from this situation, the opening in the skull can be enlarged. In case the source of hemorrhage cannot be found the wound may be packed and the flap of bone temporarily replaced. At a later day the packing can be removed and the wound leisurely inspected.

A further advantage of the large opening thus permitted is the ease with which a copious extravasation can be evacuated. The use of the mallet and chisel is well adapted to the performance of the operation.

EDITORIAL COMMENTS.

The Cleveland Medical Society, the Code of Ethics, and Sectarian Affiliation.—At a recent meeting of the Cleveland Medical Society the following preamble and resolution were presented, and, after some discussion, adopted:

"WHEREAS, The Constitution and By-Laws of the Cleveland Medical Society provide that any legal medical practitioner is eligible to membership in said Society; and

"WHEREAS, At the last meeting the amendment which was proposed to make the Constitution and By-Laws of said Cleveland Medical Society conform to the Constitution, By-Laws, and Code of Ethics of the

American Medical Association was rejected and laid on the table:

"*Resolved*, That the active membership of said Cleveland Medical Society shall be open to any legal practitioner of this city, no distinction being made in regard to the school of medicine to which said legal practitioner may belong."

The contention was made that the resolution was in conflict with the present Constitution of the Society, which permitted only regular physicians to become members. This difficulty was, however, overcome by the adoption of a motion that the word "regular" be so construed as to mean any legally qualified practitioner of medicine.

We can scarcely congratulate the Cleveland Society upon its action in this matter, for we are unable to see how good can come of affiliation with practisers of sectarian medicine. If honest and sincere in their practice, they must be wrong in philosophy; if dishonest and insincere, wrong in morals. How any reputable regular physician can meet such men professionally, on terms of equality, and to the advantage of the patient, we fail to comprehend. Now, as ever, oil and water will not mix.

While we agree with our excellent contemporary, the *Western Reserve Medical Journal*, that a code does not make gentlemen of those who are not already such, it must be remembered that neither code nor law is needed for the good people of any community. It is for those "upon the fence," as well as the outright bad, for whom restrictive legislation is necessary. As things go, there are a certain number of men, both without and within the medical profession, who require just such restraint as is exerted by the enactment of salutary laws upon the one hand and of an ethical code upon the other. If it were true that "no gentleman in our profession will knowingly consort professionally with a man of evil practices and dishonorable methods, nor will he call in consultation a man inferior to himself in knowledge and experience," there would in reality be no need of a code. Just as true is it that if there were no criminals there would be no need of preventive or reformatory laws. Besides, what course will the "superior" regular pursue when asked to consult with an "inferior" sectarian? It is, further, perhaps, "nobody else's business with whom a man consults," but frail humanity ordinarily judges individuals by their associates and their associations.

The New York State Board of Medical Examiners.—The State Board of Medical Examiners representing the Medical Society of the State of New York has made a report of its work for the year 1894, which contains a number of interesting data. The total number of candidates actually examined was 536. Of these, 470 were examined by the Board representing the Medical Society of the State of New York; 59 by the Board representing the Homeopathic State Medical Society; and 7 by the Board representing the Eclectic Medical Society of the State of New York. Of the first, 316 passed, and 32.7 per cent. were rejected. Of the second, 46 passed, and 22 per cent. were rejected. Of the third, 3 passed, and 57·1 per cent. were rejected. Seventeen candidates were rejected a second time; 6, three or more times; and 54 were unable to secure a license.

It appeared that, whereas prior to 1891 the number of physicians locating in the State of New York was from 700 to 800, there are at present less than 400. The fact, however, that there were 536 applicants is accounted for not only by an increase in the number of medical men, but principally by the fact that the State license has become a matter of such importance that most of the States having boards of medical examiners accept them as licenses to practise, without exacting added medical tests. Under the provisions of the law the Board of Medical Examiners is permitted to indorse as sufficient to practise the licenses issued by other State boards of medical examiners, provided the standards of these boards are not lower than those of the New York Board. Numerous applications from various States were received for this indorsement, but on investigation it was found in each instance that the standard was not sufficiently high to warrant approval of the documents submitted. The Board complains that the preliminary education of medical students and candidates for the licensing degree in the State of New York is not satisfactory. It finds that while the standard is far above that established in other States it is still insufficient and not on a par with the requirements exacted from students of other professions in the State. In accordance with this opinion the Board adopted a resolution declaring that the best interests of the public and of the medical profession would be materially advanced by gradually increasing the minimum requirements as to general preliminary education until no candidate be entitled to matriculate in 1897 at a degree-granting medical school who shall not have completed at least a full high-school course. The public may well congratulate itself upon the outcome of the agitation directed to its welfare and interest instituted and carried to a successful issue by the medical profession.

Dr. Daniel Hack Tuke.—The death of this eminent alienist is announced in the cable dispatches from England. Dr. Tuke was a grandson of William Tuke, the founder of the York Retreat, the celebrated Friends' Asylum, in which, for the first time in Great Britain, rational and humane methods were employed in the treatment of the insane. He was educated at St. Bartholomew's Hospital, where he was a fellow-student with that distinguished Friend and ornament to our profession, Mr. Jonathan Hutchinson. For a time Dr. Tuke was Resident Physician at the York Retreat, but a progressing lung-trouble interrupted his professional work for many years, during which he lived at Falmouth. He kept close touch, however, with his special work, and issued in this period, with Dr. Bucknill, the well-known *Manual of Psychological Medicine*, and the *Influence of the Mind Upon the Body*, both of which were reprinted in this country.

Early in the seventies his health was so far established that he removed to London, where for twenty years he has been an active worker in promoting the best interests of psychology. For many years he was joint editor of the *Journal of Mental Science*, and he has year by year issued many valuable monographs, such as *Insanity in Ancient and Modern Life*, 1878; *Chapters in the History of the Insane in the British Isles*, 1882; *Sleep-Walking and Hypnotism*, 1884. In 1892 appeared the *Dictionary of Psychological Medicine*, which he edited with great skill and care. In 1884 Dr. Tuke visited the United States and Canada, and made a systematic inspection of the asylums of both countries. The results of his visit appeared in a work entitled *The Insane in the United States and Canada*, 1885. He entertained for this country that warm feeling which characterizes so many of the members of the Society of Friends in England, and while here he made himself very popular, and left behind most pleasant memories. He had, in truth, a loving and gentle spirit, zealous ever for the good of his afflicted brethren, zealous always for the honor of the profession. His life affords a noble example of splendid work accomplished under the adverse circumstances of ill-health; and his name will be written (with those of his father and grandfather) among the Abou-Ben-Adhems—those ministers of God to men, who have "in much patience, in affliction, in necessities, in distresses," labored to lighten the heaviest burden of a heavily burdened humanity.

Defective Eyesight and Color-blindness in the Mercantile Marine.—Perhaps even more so than that railway-engineers and other employés on railroads should be free from defects of vision, and especially color-blindness, is it essential that the officers and men on board ship should possess such freedom from imperfect eyesight. Systematic effort is making in England to attain such a desirable state of affairs, and should find ready imitation in all civilized countries. It appears that in the year 1852 the Liverpool Board of Trade issued an order compelling vessels at sea to carry at night bright and colored lights, so as to indicate their position to other and passing vessels. A few years later attention was called to the fact that accidents could not be prevented by this means if the sailors were poor-sighted or color-blind; but a long time elapsed before practical notice was taken of this important observation. It was not until 1877 that the Liverpool Board of Trade promulgated rules and regulations dealing with this question, and new tests were issued to masters and mates in the mercantile marine in 1894. Carried out by competent medical examiners, these tests are in themselves satisfactory; but their usefulness is neutralized by the fact that they become compulsory only when a man enters for a second mate's certificate, instead of when he begins his career as a sailor. The evils of this course are (1) that defective vision and color-blindness may exist in all men in the mercantile marine below the rank of second mate; and (2) that such men, after having spent many years in preliminary work, find themselves cut off from advancement by reason of the discovery of their defect. The remedies proposed are that no one should be allowed to enter the mercantile marine who is not shown by adequate tests to be free from defects of vision, more particularly as regards form and color, and that every navigating sailor should, on going to sea, be compelled to possess and display a certificate of good vision. Other employment should, as far as possible, be provided for those already in the service who happen to suffer from serious defects of vision.

The Children's Aid Society of Pennsylvania.—We cannot forbear again calling attention to the splendid work being done by the Children's Aid Society of Pennsylvania. The work of this organization is not pursued upon conventional lines; the Society has not founded a "home" in which it cares for large numbers of children. On the contrary, its object is the placing of children who have no one else to care for them with families willing to look after them. In the past the Society has, from want of adequate means, found homes for these children in families willing to keep them without remuneration, but experience has taught that better results are attained by an arrangement in conformity with which a certain amount of board is paid for each child, and whose supervision is continued by the Society. The work has already been so well organized that the number of applications for children is in excess of the means of the Society for their disposition. The advantages of the plan seem so obvious as scarcely to justify elaboration. These unfortunates are thus at once removed from influences likely to react unfavorably upon their moral, mental, and physical development, and placed amid others calculated to exercise the opposite effect. Useful citizens are made of those that, uncared for, might go to swell the criminal and defective classes.

The Society has had under its care, during the year 1894, 598 children, of which number, 104 passed from under its care. In addition, 466 women, each having one child, were rendered self-supporting by being placed at service. The Western Soup Society has fitted up a part of a commodious house for the use of these homeless mothers with children, with the object of inducing the mothers to keep their children with them, rather than to surrender them into the care of others. Good places are found for these in families that are willing to take a mother with her infant into their employ at low wages. Temporary lodging, while awaiting situations, is given by the Soup Society, the cost of board being deducted from their wages after the women are placed at service.

The work of the Society is distinctly humanitarian and deserving of the warmest encouragement and support. Charles E. Peterson, 321 South Twelfth Street, is the Treasurer, and will be glad to receive contributions.

More Play-grounds for Children.—The Board of Education of Philadelphia contemplates the opening of school-yards after school-hours, so that children may use them for play-grounds. There is no reason why the brick pavements in such yards should not be removed in order to prevent broken limbs and other accidents which are liable to occur when children are obliged to play in such paved yards.

The movement for breathing-spaces, city parks, and children's play-grounds should receive all encouragement. The majority of children must remain in the city during summer, and the trolleyed streets and filthy courts and alleys are not fit for children to play in.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting held January 23, 1895.

"Heredity in Insanity" was the title of a paper by DR. ROBERT H. CHASE. It was pointed out that the most common of all diseases is insanity, and the most common cause of insanity is heredity. In no class of disease is the transmission of a predisposition to ill-health more potent or more evident than in insanity. This fact renders the subject one of the most important in the range of medical science.

The reasons for this great phenomenon are not hard to find or difficult to understand. If the mental and physical traits were not transmissible, then there would be an end to all training and all development. As one writer aptly puts it:

"If the child did not inherit the result of all that had gone before, with additional power of development on his own part, all social growth would be rendered impossible. The torch of civilization is handed from father to son, and, as with the idiosyncrasies of mind, so the very body itself exhibits well-defined marks of its parentage."

Thus it is undoubtedly that there is a great fundamental law of nature that the attributes of the parent descend to the child. This seems to be particularly true of the failings, the defects, the infirmities of the parent.

There have been opponents to this proposition, particularly as regards the hereditary character of insanity. Dr. Bucknill has thrown doubts upon the importance of inheritance and has said that if insanity be so easily transmitted from parent to child, how is it that so many in a family escape? The reply to this argument sweeps it away entirely. First, it is a well-known fact that a new generation may escape entirely, or to a large extent, the mental taint of their progenitors; but who can be certain that the taint is actually absent and not held in abeyance? Second, the study of hereditary transmission of various parental peculiarities shows that heredity is prone to select only certain individuals in a family; take, for example, the peculiarity of the presence of an extra finger or toe. This anomaly may run for many years in a family, selecting only a few individuals, or even one alone in a generation. Third, the more obscure fact in the law of heredity that a tendency may be transmitted from one generation to the third through a second generation which may show no development in the person transmitting it. One of the most beautiful illustrations that we have of this freak of nature is seen in hemophilia, a daughter who is not a bleeder transmitting the tendency to bleed from her father to her son.

When we become better acquainted with this subject of heredity doubtless we shall find that there are well-defined principles by which mental taint is transmitted; already we know that heredity in insanity follows, to a great extent, certain definite tendencies. In this manner insanity may be transmitted directly as far as kind goes, so that the hypochondriacal parent may have a hypochondriacal child, although frequently the inheritance may be altered in form, as a maniacal parent having a melancholic or epileptic child. Another proneness of inheritance seems to be the transmission of the tendency to take on disease under similar conditions, such as age or childbirth. Thus, one family inheritance is a tendency to pass into a state of weakmindedness with melancholy at a certain period of life. Likewise, instances are recorded in which mother and daughter have suffered from puerperal insanity.

In taking up the subject of heredity in insanity in as scientific a manner as our present data will allow, it is well to define exactly what we mean by the term. By heredity, in mental pathology, we mean an original predisposition to mental alienation transmitted to children from their parents.

This definition becomes necessary when we come to study the frequency of the transmission of insanity, for different observers vary in their figures, as a result, we shall find, largely of their variance in the definition of heredity. For example, Marcè claims that we find some antecedent taint in nine-tenths of all cases; Esquirol, on the other hand, found this predisposing cause in one-fourth of 1375 patients whose histories he examined. Figures of other observers vary between these extremes, in consequence undoubtedly of the latitude allowed by the different observers in their search for previous cases of insanity in the families of the patients so afflicted. Those observers whose percentages run very high have included almost any connection by blood, while those whose percentages are lower have limited their examinations to direct ancestors, as parents, grandparents, and great-grandparents. In this dispute the medium course in estimating the number of patients whose insanity is due to inheritance is the safer one. On examining the figures of all the various observers, it is a modest estimate to say that the figures vary between 40 and 60 per cent.

There is a nomenclature in the study of this subject which it is necessary to comprehend to follow it intelligently. Heredity, when it is attributed to parents, is *immediate;* when it is traced from grandparents, having skipped the parents, it is *mediate*. When it has existed for many prior generations it is called *cumulative*. It may be on the side of both parents, in which case it is called *double*, or *from convergent factors*. When it is derived from one parent it is *simple*, either paternal or maternal. According to Esquirol, the latter is the more serious form of the two; it is also three times the more common.

When hereditary insanity appears in the child at the time that it appeared in the parent it is called *homochronous*. When it appears in children before it is seen in the parent it is called *anticipatory*. When the hereditary taint reveals itself by a mental disorder identical with that of the parent it is called *homologous;* when it is modified in passing from one generation to another it is called *dissimilar*, or *transformed*. When it becomes more and more intensified by transmission it is said to be *progressive;* if it is alleviated by a series of fortunate crossings, it is *regressive*.

The forms of mental alienation that are more predisposed to transmission are undoubtedly suicidal, reasoning, and the several forms of periodic insanity; while acute mania and melancholia compromise the family to a much less degree. In pursuance of this subject Dr. Règis' recent work is interesting. This observer has taken up the biologic features of insane families and has developed the theory that heredity in mental alienation presents itself under three morbid types, with clearly defined characteristics:

1. The neurotic, or neuropathic type, which originates in the neuroses and gives rise to neuroses and neuropathic insanities.

2. The cerebral or congestive type, originating in cerebral disorders and giving rise to cerebral affections, complicated, it may be, with insanity.

3. The vesanic type, originating in pure insanities, giving rise also to pure insanities, or vesania.

The special evolution of each of these hereditary types, according to this authority, permits to a certain extent the foretelling to what category of mental disorders the members of a family are particularly disposed. Thus, for example, general paresis does not arise from insanity and does not engender insanity. Like the cerebral diseases, it is born of cerebral affections, and gives rise to the same. It follows that as general paralytics are not descendants of the insane, and do not produce the same, their children escape vesanic heredity; and if they are doomed to any special class of disease by reason of the general paralysis of a parent, it is evidently not to insanity but to cerebral affections of all kinds. Although the biologic study of the family history of the insane of these various types has but recently been touched upon by observers, yet this field is rapidly widening, and it is probable that the day is coming when it will be possible for a physician to formulate in cases of hereditary predisposition scientific rational opinions, not merely a response empiric, so to speak, made solely to reassure the interested parties.

The prognosis when there is a hereditary predisposition to insanity is unfavorable as to permanent recovery; although it may render the likelihood of a primary recovery more probable, yet the possibility of a permanent cure is less probable. Curiously enough, some observers have claimed a higher percentage of recoveries in hereditary cases than in non-hereditary cases —in the table of the Crichton cases, in which in a large number reported the percentage of recoveries in hereditary cases was 36 per cent. to 32 per cent. in the non-hereditary. But the great mass of statistics exhibit the opposite result. Krafft-Ebing has demonstrated the fact that in cases of hereditary disease that were marked by sudden explosions of insanity the prognosis was favorable, while in those that were characterized by a long incubation it was unfavorable. The Crichton cases happened probably to contain a large percentage of the former class. The great tendency of hereditary insanity is to relapse. The diagnostic value of a hereditary tendency to insanity depends largely on its degree. Thus the insanity of one parent would indicate a less degree of predisposition than that of one parent and an uncle, or still less than that of a parent and a grandparent, or of both parents. Again, the insanity of a parent and a grandparent, together with that of an uncle or an aunt in the same line, may be held to indicate a stronger predisposition than even the insanity of both parents.

The significance of the insanity of parents will depend to a large extent upon the period of its onset. The insanity of a parent occurring after the birth of a child, if it arose from a cause adequate to excite it without previous predisposition, would be held, of course, as of no value in the formation of a hereditary tendency.

The insanity of relatives more remote than parents, uncles and aunts, brothers and sisters and first cousins, is not worth anything except in corroboration of nearer and weightier facts. But the influence of other related diseases to insanity occurring in those near akin, such as eccentricity, alcoholism, epilepsy, hysteria, hypochondriasis, vicious or criminal tendencies, etc., may be of great import.

It will thus be seen that the evidence of hereditary predisposition may be of such a character as to render insanity in a patient an event in the highest degree probable; or, on the other hand, it may be so weak as to add a scarcely appreciable amount of probability to the character of the disease.

The treatment of heredity in insanity is, after all, the most important, because the most practical side of the question. Of course, the most decisive way to treat this subject would be to stamp it out by forbidding the marriage of persons so tainted, but unfortunately, as in our syphilitic and tuberculous cases, this is impossible; so our efforts must be directed to preventing the appearance of insanity in such cases, or, if impossible, to ameliorating its condition when it appears. In children of such parents, method, patience, persistent command of temper, self-denying industry, and much knowledge of child-nature are necessary. As to choice between home and school treatment, it is impossible to decide in all cases off-hand. Some do better at home, some do better at school; few will do well at home, however, when it is impossible to be strict without being stern, or to carry out the necessary discipline without setting aside the claims of natural affection. The selection of the proper person to carry out these plans of discipline is by far the most important factor in the early history of the case.

Again, a sound mind needs a sound body; and exercise, food, and raiment exert marked control over the health of these children. Their lives must be a happy medium between the Scylla of over-exertion, over-discipline, over-study, and the Charybdis of the antithesis of these factors.

When the child has become the man, or at least when he comes to be his own master, then is the time of greatest trial. The physical and moral storm of puberty must be encountered, and great temptations have to be met with less guidance. When the outbreak is imminent the problem arises: Should the youth or the man continue or stop his regular occupation? This is a question that cannot be answered without a study of the individual case. In some instances it is better for the patient to do this; in some worse. The only general rule to follow is that if the calling is attended with anxieties that weigh upon the ailing mind, it should either be given up for a time or its burden should be lightened.

Should the threatened patient travel? This is an easy solution of the problem and an error often into which many physicians fall; it is so easy to order the patient away, that it is adopted with more frequency than wisdom. Change of scene may do good, but constant change of scene, with its labors, vexations, and trials, especially in a foreign country, may do much harm. A threatened case of insanity should not be sent to travel without guarantee that proper care and efficient watch will be provided for him. Travel should include due provision for care and protection, the right admixture of rest and fatigue, change and repose. Under these circumstances it may be a very fair thing to try.

DR. MARTIN W. BARR next read a paper on "The Influence of Heredity on Idiocy." Throughout the history of education and of medicine no point has so engaged the attention of the philosopher and the scientist as the influences of environment and heredity. These influences upon our physical being, repeated through successive generations, resolve themselves into a law, a law as unalterable as that of the Medes and Persians—a law founded upon fundamental truths and verified in the experiments of physiologic science.

The aim of educational and medical science is one, viz., to secure to the individual a sound mind in a sound body, so that all that touches one must find its prototype in the other. In this more than aught else, if one member suffer, all the members suffer with it.

This law of balance and proportion we recognize in the forces of Nature, in the applied arts and sciences, and we are quick to note the evil effect of the least deviation from this rule.

In a nature so complex as man's—a mechanism so finely ordered—none can deny that the same principle is but intensified.

Here, therefore, in natural sequence, the *psychologic* follows the *physiologic* research, nay, rather joins hands in this effort to restore health to the mind or to prevent degeneration; and, acknowledging the sins of the father transmitted in the *body* to the third and fourth generations, would fain seek in the springs of life itself the influence of heredity upon the mind—the secret and causes of idiocy. Most arrogantly we call ourselves "the heirs of all the ages" in all good gifts, but we are slow to acknowledge the serpent's trail in our Eden. Our vanity is sensitive, and recoils naturally from the thought of blemish in our own—physical or mental—an ancestry, either ignoble or unfortunate. We do not, and we will not, except under protest, receive the law of heredity of ill.

Convinced that it is logical, still we seek proof in statistics. The gathering of statistics under these circumstances is difficult. Parents and friends are loath to accept such evidence, and, actuated by false shame, still more loath to impart information, especially when there is a neurotic taint. The physician, in many cases, feeling that he is betraying a confidence, keeps no record, and the literature on the subject is, therefore, most meager. Thus, when we begin to sift the matter as we should like, we are frequently unable to verify our conclusions. So in many cases the causes of idiocy remain unexplained, closeted within the secret recesses of nature.

But the field of research, with all its difficulties, is broad and is practically unexplored. Before going into statistics, however, let us consider, for a brief space, opinions of deep thinkers on this subject.

Mercier says: "The first and most fundamental law of heredity is that *every attribute of the parents tends to be inherited by the offspring*. Inheritance is the law, non-inheritance the exception." It will be observed that he does not say they *are*, but that they *tend* to be inherited, and the question therefore resolves itself into this, either the offspring does or does not resemble its ancestors. If the former, then there is an hereditary law; if the latter, there is not.

Strong as this is we find in Montaigne a stronger thought:

"Is it not marvellous that this drop of seed from which we are produced should bear the impression not only of the bodily form, but even of the thoughts and inclinations of our fathers? Where does this drop of water keep this infinite number of forms? And how does it bear these likenesses through a progress so haphazard and so irregular that the great-grandson shall resemble the great-grandfather?"

Blandford says: "Two laws of nature are concerned in the production of these phenomena. One is that peculiarities and abnormalities are apt to recur in descendants for many generations; the other, that there is always a tendency to return to the type of health in beings which have sufficient vitality to perpetuate their existence and carry on their race for successive generations."

We do not always produce an idiot from a neurotic family.

Again, one or even more of a family may be insane or idiotic, the others normal, showing the taint concentrated, as a result possibly of surrounding conditions and temperament of parents at the time of conception, combined with prenatal influences upon the mother.

Thus, every idiotic child bears the mark of some inherited tendency from some ancestor.

I shall here cite a case among my own patients, in which a male idiot, born of imbecile parents, possesses the face and form of the mother, with the disposition of the father, a type of both physical and moral imbecility.

Neuroses are frequently interchangeable in transmission from generation to generation, and there are two great laws—the reversion to the original healthy and perfect type when the taint is less noticeable in generations, until it at last is not found at all; or it becomes more pronounced, and a simple nervous disease may appear in successive generations in the form of a pronounced neurosis.

From Ireland[1] we have the following: "Of all known diseases, perhaps idiocy is most frequently propagated by heredity."

Moreau, of Tours, affirmed that heredity was found in nine-tenths of his cases, but he gave no statistics.

According to George Wallington Grabham,[2] heredity is the chief agent in the production of idiocy. Although in his statistics he collects but 18 per cent., he is convinced that the taint exists in a far greater proportion.

Dr. Shuttleworth, in a recent personal letter, writes: "My opinion is that heredity plays a very important part in the production of idiocy, though we cannot prove the frequency by statistics so completely as the fact is impressed on one's mind by intercourse year after year with the relations of acknowledged idiots and imbeciles.

"Taking only the friends' statements, we should be much misled, and for that reason I declined, when at the Royal Albert Asylum, to publish each year any table of causes. . . . . But as one got to see more of the relatives, one gradually accumulated a considerable body of evidence, and this has been summed up and compared with Dr. Beach's experience at Darenth." These observations are as follows: The most frequent hereditary factor is pulmonary tuberculosis, which is found existing in 28.31 per cent.; inherited mental weakness, 21.38 per cent. (16.47 per cent. family history of insanity, 4.69 per cent. family history of imbecility), whilst in 20 per cent. there was a family history of neuroses.

Fletcher Beach subsequently made some further studies alone at Darenth, and found heredity in 76 per cent. of these cases.

---

[1] On the Diagnosis and Prognosis of Idiocy and Imbecility, p. 1.

[2] Remarks on the Origin, Varieties, and Termination of Idiocy.

In 1856 the Legislature of Connecticut[1] appointed a commission to investigate the causes of idiocy. The questions propounded were as to whether there had been idiocy, insanity, blindness, deafness, epilepsy, or any other defect, mental or physical, in the immediate or collateral family of the idiot.

The commission reported that out of 164 cases it found 70 in which heredity was undoubtedly the cause: in 10 cases idiocy in the parents; in 6 in the various relatives; in 6 insanity in parents; in 8 insanity in relatives; in 8 epilepsy in parents or relatives; in 2 blindness; in 1 melancholia in father; in 13 dementia following insanity in relatives; and in 16 one or more of the defects mentioned, but not designated.

In the census of 1873, taken at Berne, 55 per cent. of the idiots came from neurotic families.

Dr. Langdon Down,[2] who has made an interesting series of investigations in 2000 cases, reports 45 per cent. as caused by various neurotic affections in one or both parents. If the mother were afflicted, the first children born were sufferers; if the father, the later children.

Haller cites the cases of two imbecile women of noble birth and immense wealth who married, and many of whose descendants for more than a century, even to the fifth generation, were idiots.

Esquirol,[3] reports the case of an idiotic woman at the Salpêtrière who bore three idiotic children.

Dahl[4] made careful comparative studies of the ancestry of 169 idiots and 151 insane. In the former he found that 84, or about 50 per cent., had insane relations. Among the latter there were 58, or about 38 per cent., whose relatives also presented marked symptoms of idiocy and insanity. Among these the parents of 18 insane and 21 idiots, about 12 per cent., also exhibited some mental defect. Among the idiots there were two cases in which both parents were mentally tainted, six in which the father, four in which the mother, four in which some or all of the grandparents, and five in which the great-grandparents were afflicted with mental disease. It will be noticed that the great-grandmothers predominated in transmitting the taint, but Dahl gives no explanation of this.

Dr. James R. Dunlop reports the case of a weak-minded father and mother who had seven imbecile children. He was so much interested in the case that he made a number of careful investigations. For four generations there had been some evident neurotic taint, but it was not marked in the third. The progenitor was a neurotic, and was married to a fairly intelligent woman. To them were born four children, three males and one female. The female was an imbecile, and had a son, in no way peculiar, born out of wedlock, but whose father she subsequently married. She had no other issue. Of the males, one is reported sane, one feeble-minded, and another eccentric if not imbecile. The last married a healthy woman eleven years younger than himself. They had eleven children, seven of whom were imbecile or idiotic. One, Jean, has had an illegitimate daughter who was said to be normal. One, Thomas, a hypochondriac, was said to be peculiar in looks and manner, but not weak-minded. He married a sensible woman, and had an imbecile child. James, sane, but peculiar in manner, irritable, and fretful, had eight children that were perfectly healthy.

Fletcher Beach also quotes an interesting case in which the predisposition can be traced through four generations: G. B., aged fifteen years, an imbecile, was paralyzed on the left side. Her great-grandfather was not in full possession of his senses. The grandfather was reserved, and the grandmother excitable and peculiar. The father was a neurotic, ill-tempered and morose. The father's two brothers and one sister exhibited no peculiarity, but the oldest children of both brothers exhibited the same peculiarity as the patient (G. B.). The sister's oldest child is also peculiar. From the father springs G. B., whose eleven brothers and sisters died of spasms during dentition. It will be seen by this that the neurosis running through the family touches the third generation but lightly, and intensifies itself in the fourth.

Two family histories of my own patients are interesting studies in heredity:

A. B. was an apathetic idiot. Huntington's chorea has existed in the mother's family for many generations. The maternal grandmother was choreic, the maternal grandfather tuberculous. Of this marriage there were born seven children; the order of birth, ages, and sex were unknown, with the exception of the mother of A. B. Three children are alive and married, and extremely nervous. They have children said to be normal in every respect. The four deceased children, including the mother, died of chorea. The paternal grandfather and grandmother were both strong and healthy, and lived to unusual old age. Their issue consisted of nine children, the sex, age, and order of birth being unknown. All were healthy. The mother of A. B. was always delicate, and three days after marriage was attacked by chorea, of which she died after twenty-three years. She had eight children, the oldest two—male and female—said to be normal. Both are married and have healthy children. The third is a female, and is deaf and dumb; the fourth is a male, and imbecile; the fifth, A. B., is a female, and an idiot. Three children were born after this one, of whom nothing is known except that they died in early infancy of epilepsy, diarrhea, and one was stillborn.

H. W., a high-grade imbecile, was the eighth child, and the first-born of twins in a family of fifteen, nine of whom are dead: four from convulsions in infancy, two stillborn, one from scarlatina, and two, including the patient, of meningitis. Of the six children living, five are said to be normal, and one a shameless harlot, who is practically a paranoiac. Both father and mother came of pronounced neurotic families. The father was peculiar, morose, intemperate, and died in his fifty-first year, of apoplexy. His first cousin was an imbecile. The mother is considered very peculiar.

Howe[1] tells of three towns situated in close proximity to each other in which are a number of families in which both parents and children are imbecile. He tells also of an indigent female idiot living in one town who married, with the sanction of the town authorities, a male idiot, who was not a pauper, with three idiotic children as a result.

[1] Causes of Idiocy, p. 78.

Dr. Isaac N. Kerlin, my master in the work, in 1880 presented a valuable paper on the "Causation of Idiocy based upon the Analysis of One-hundred Idiots and Imbeciles." He found that 28 per cent. were caused by insanity and feeble-mindedness, and 57 per cent. by various nervous diseases.

In my own experience, based on a careful examination into the family history of 1044 idiots, I find 397 families, or 38 per cent., with a history of insanity or imbecility, and 225, or about 21½ per cent., with a history of various neuroses.

There is one point so nearly allied to our subject as to demand at least a passing consideration.

Consanguinity is commonly accounted a fruitful cause of idiocy; but comparative investigation shows, first, children having both mental and physical defects, the offspring of healthy unrelated parents; second, perfectly developed children with no personal peculiarities whatsoever, the issue of consanguineous marriages. This would lead us to accept the statement that consanguinity has but little if any influence in the production of idiocy, unless there be some hereditary neurosis.

Heath maintains that if the blood be pure and uncontaminated there will be no bad results from such marriages.

A confirmation of this may be found in the history of the Hebrews, which shows repeated examples of consanguineous marriages, the intermingling of pure blood giving only good results, idiocy being the exception rather than the rule.

The statistics that I have been able so far to gather run thus: In 1865 the population of Batz, Brittany, numbered 3300. Five marriages took place between the cousins-german, thirty-one between second cousins, and ten between those of third degree. The issue of the cousins-german numbered twenty-three children, free from all disease both mental and physical. The second cousins had 120 children, normal in every respect, and the issue of the cousins of the third degree numbered twenty-nine children, also perfect. Two women were sterile. Insanity, idiocy, and nervous diseases were unknown in this community.

Dr. Kerlin found but 7 per cent. of his cases examined directly traceable to consanguinity. In my own examinations of 1044 idiots I find but 3⅓ per cent. On the other hand, consanguineous marriages of persons with the least neurotic taint must always be marked by deterioration of mental power. Naturally, if the taint exist in both parents, the force is but intensified, and idiots are likely to be produced with peculiarities accentuated. A notable example of this is found in Switzerland, where, among the people secluded from the outer world in mountain fastnesses, intermarriage has been going on for centuries. Here, by repeated intermarrying, neuroses are preserved intact and idiocy ripens.

Among my own records I find an interesting case that I herewith present:

J. F., an excitable idiot, was born of cousins-german, in whose families were marked neuroses. The mother was always delicate, and finally died of pulmonary tuberculosis. The father was emotional and silly to the verge of imbecility. The following is an account of their offspring: The family, a large one, numbered eleven in all. Four died in early childhood (from diseases unknown); three are living, but of them I have no history, and of the remaining four I have records. One was the first born, a female, and was deaf and dumb; the next was the second born, also a female, and was epileptic; the next was the third born, a male, and was an idiot; and the last was the eighth born (the patient), and also an idiot.

Frequently idiocy appears as the outward and visible sign of the mental deterioration of a family in which intermarriage has been frequent, especially of one that has been noted for its intellectual qualities, and, according to Griesinger,[1] it is a mark of degeneration in a race whose blood has stagnated, as, for example, in the Asylum of L., where many of the proudest names in England are borne by drivelling idiots.

Esquirol says that it is simply impossible to enumerate the idiots in the noble families of France, among whom intermarriage is frequent, and also among the Roman Catholic families of England and Scotland.

We have considered to-night, not possibilities or chimeric maybes, but grim *facts* gathered through years at much cost and pains, by patient, earnest, thoughtful, philosophic minds. Let us come up from their past with the lamp of experience they have placed in our hands to study the present and verify their conclusions.

What are the signs that tell of this enemy who shall come in like a flood? What standard shall we lift up against him? It is said that the pulse of a nation's prosperity is found in its marts—the danger-signals are read at its bourse.

Where shall we judge of the intellectual status of a nation but in its educational centers. Schools, colleges, universities multiply with unprecedented rapidity over a land that has just celebrated its fourth birthday among the centuries of civilization.

Through these corridors, out from these doors, press in mad haste for the arena of life, young men and maidens, warm blood, freighted in many cases so fatally with the miasma from some remote ancestor, often doubled and quadrupled in intensity by consanguineous marriages, waiting but for this unhealthy and artificial atmosphere to develop into abnormal growth.

Do we ask why are the hopes of fond parents so often blighted? What becomes of these fair buds of promise?

Go find the answer in those other schools that are growing apace in our midst, dotting from ocean to ocean our own fair land, while others stretch out appealing hands to us—schools public and private that offer no prizes, or hope of diplomas, yet that are also multiplying with frightful rapidity in response to the agonized cry of the Rachels weeping for their children, and who will not be comforted, because they are not.

The attention of many medical men is drawn to the influence of intemperance in parents as a cause of idiocy. The statistics, however, are too meager and the statements too unreliable for us to base any definite conclusions upon them. The Connecticut commission found

---

[1] Mental Pathology, p. 349.

32.34 per cent. My own experience shows 18.38 per cent. Langdon Down lays special stress upon the intoxicated state of the father at the time of conception, an opinion advanced years ago by Toussenel,[1] and verified in one instance in my own practice.

Ludvig Dahl agrees that to the abuse of brandy by the fathers, and also to some extent by the mothers during pregnancy, may be assigned the most important influence in the production of the large number of idiots in Norway.

Upon the influence of pulmonary tuberculosis, held by many as an important factor, I have not entered, as it is largely embraced in the points already elaborated.

The last example I have to offer, and by far the most appalling on record, is that of the family known as "The Tribe of Ishmael," whose history traced through a period of forty years shows descendants of one unclean, neurotic man, multiplying by consanguineous marriages into two-hundred-and-fifty families, numbering some five-thousand individuals, whose continuous criminal record has poured over the Northwest a flood of imbecility and crime.

Can we, in the face of such evidence, refuse to accept inheritance as one of the fundamental laws of life?

The mark of the beast is ever present—the spoor of the wild animal remains—and to-day we trace it not only to the third and fourth generations, but on *ad finitum*.

Dr. John B. Chapin then read a paper entitled "Heredity, its Relation to Insanity and Idiocy." There has always existed a deep-seated conviction that certain diseases are transmissible by inheritance from parent to offspring. This conviction is strongly fortified by an array of statistics that, if accepted without reservation, might in themselves establish the fact. It is quite common to place insanity and idiocy in this category. So prevalent is the belief that insanity is directly transmitted by inheritance that in medico-legal proceedings it is usual to consider it a strong defence to show that insanity existed in the family of a person charged with crime. So well grounded is the opinion that insanity may be due to a direct inheritance that its existence is the shadow that darkens households, affects plans of domestic arrangements, blights the happiness, and shapes the destinies of a large number of persons. Doubtless the mystery that surrounds the complex operations of the mind, the reported results of observations by physicians, the absolute ignorance of the laws of heredity, beyond the ken of human comprehension, have together conduced to the acceptance of speculations as actual results of well-established facts. Doubtless, religious views, coincidences of events, overworked facts, and ignorance have exercised an influence in the formation of opinions on this subject and their unquestioned acceptance.

That every species produces its kind is a universally recognized law. That there are physical and psychic characteristics that belong to the individuals making up the many nationalities and that are transmitted and preserved from generation to generation; that there are so-called temperaments that have a certain uniformity of physical and psychic development, so that they may be recognized and described, is a matter of common observation. Darwin has also presented the theory "that each of the atoms or units constituting an *organism* reproduces itself."

Heredity manifests itself in family likeness, the hair, gait, height, form, temperament, and physical development. The "atoms or units" proceed in accordance with some uniform law of development, so that, however the stock may be crossed, the rule is that man transmits his exact physical counterpart, subject to modification due to environment, climatic conditions, etc. That the vigor of the stock does not abate is witnessed in the fecundity of the human race.

Whether a similar unvarying law governs the transmissibility of psychic qualities may be a question or in doubt. The same consensus of opinion, however, is disposed to conclude that mental traits are transmitted from parents to children in the same degree that physical qualities are inherited. This is only partly true, but the exceptions are so numerous that it may be considered a chance that the children will possess the psychic qualities of the parents. It has been demonstrated by histories of families in England that strong qualities of mind have been transmitted through generations. On the other hand, this society may be familiar with the history of a family in New York State comprising twelve-hundred persons of several generations, traced by Mr. Dugdale, who as paupers, lunatics, idiots, criminals, murderers, and prostitutes were estimated to have cost the county of Ulster the enormous sum of one-million-three-hundred-thousand dollars ($1,300,000). In making inquiry into the ancestry of a certain family in Yates County, New York, it was ascertained definitely that twenty-two insane persons, criminals, paupers, or idiots could be traced in two generations to an abandoned woman. The influence of marriages of consanguinity deserves a notice in this connection. Dr. S. M. Bemiss collected some statistics that show the nature of the deterioration that may come from this source. Of ten instances of incestuous commerce 31 children were born; 29 were defective, viz., 19 idiots, the remainder epileptic or deformed. Of 823 marriages of cousins, 3942 children were born, of whom 1105 were defective, 145 deaf and dumb, 85 blind, 308 idiotic, 60 epileptic, and only 38 insane. The results of consanguineous marriages furnish an heredity of physical imperfections rather than of psychic disease. Notwithstanding these results, and the necessarily crude notions that commonly prevail, as well as the probabilities they suggest, it must be stated that there is absolutely no unvarying law of transmission established by these reported facts, because of well-known exceptions.

The average normal psychic development is not so often due to transmission or inheritance as to influences of environment, education, the degree of mental receptivity, together with the evolution that goes on from age to age. The quality called genius and knowledge does not seem to be transmitted by inheritance, but a receptive faculty, a capacity to acquire knowledge and evolve ideas, may be an heredity. The term heredity is well defined as "the principle or fact of the transmission of physical or mental qualities or tendencies from ancestors." (Gould's *Medical Dictionary*.) The instances of the transmission of "qualities and tendencies" that have been cited, and those results that sometimes appear after consanguineous marriages, are marked examples of both physical and psychic deterioration, mental and moral degeneration, of mental and bodily failure—increasing in intensity with successive generations, and of those defects that follow such marriages, according to the principle of reversion or degeneration, in a backward direction, even to the extinction of the line of succession. Dr. Seguin observed: "I have not, to my knowledge, ever had to attend an idiotic son of an idiot, or even the son of a man of weak intellect."

---

[1] "On sait que les enfants se ressentent généralement de l'influence passionelle qui a présidé a leur conception. La plupart des enfants procrées dans l'ivresse bacchique."—Monde des Oiseaux, p. 106. Quoted by Ireland, Idiocy and Imbecility, p. 27.

An hereditary disease is one that may be transmitted directly from parent to child, Admitting that it is established that certain physical diseases are inherited, can it be shown that insanity should be classed in this category? If it is not an *inheritance*, may it not in certain cases, be ascribed more properly to the results of heredity? And within what limitations? Individual opinions, formed from a knowledge confined to a limited number of cases lead some to a conclusion without further reflection. Psychologic theorizing leads others to collect data to support their views, and a personal element comes to enter in to throw doubt upon the value of any statistics. Hospitals for the insane have contributed their quota, which their medical officers have reported. Thus, Esquirol reported that 0.33 per cent. of his cases were hereditary; Brigham, 0.26 per cent.; Thurnam, 0.32 per cent.; Aubanel, 0.4 per cent.; Burrows, 0.85 per cent.; Hood, 0.9 per cent.; Moreau, 0.90 per cent. These statistics were all compiled prior to 1860, and cover a period of fifty years. What rule was applied in their preparation does not appear. The wide range of results at once suggests a great lack of uniformity of material, wide differences in opinion about what constitutes inherited insanity, and a wide latitude in speculation. Since 1860 the percentum of reported cases of hereditary insanity has decidedly fallen off, although insanity has greatly increased. In some reports of hospitals neither "hereditary insanity" nor "heredity" appears in the list of assigned "causes." In other hospitals the number of cases assigned to heredity has been steadily declining. At the Pennsylvania Hospital for the Insane, among 10,562 cases heredity was assigned as a cause of insanity in eight cases in every thousand. At the Utica (N. Y.) State Hospital, where statistics have been prepared with a considerable degree of uniformity, the annual percentage varies from four to six. While in some of the American hospitals it is somewhat larger than that just named, generally the reported percentage in European hospitals is very much greater than in this country. Possibly this is owing to different social conditions that prevail, in-breeding, debauchery of parents, greater mental and physical deterioration, the lines on which observers have made up their statistics, as well as the tendency to accept and follow views of recognized authorities. Whatever may be the explanation of the differences of reported results, it is apparent that in recent years the tendency is to attach less importance to the assumption that insanity is directly transmissible by inheritance. By many it is wholly ignored as a direct factor in the production of any considerable amount of insanity—at least inheritance is not named as an assigned cause. If the statistics presented had been prepared by observers holding the same theories, and from exactly the same data, there could be but one conclusion—that the inheritance of insanity (if there be such a thing) is rapidly diminishing.

Referring to personal observations, an examination of three-hundred-and-forty seven patients admitted during two years to the Pennsylvania Hospital showed that the probable and direct causes of insanity in one-hundred-and-eighty cases were neurasthenia, or nervous exhaustion from overwork, strain, and worriment; some form of general ill-health; the puerperal state; septic conditions, etc.; and the element of inheritance did not appear or was not ascertained. The remainder were cases of paresis and other forms due to brain-degeneration, senile failure, or organic disease, some with a history of marked heredity. Twenty-seven, or 14 per cent. only, had a family history sufficiently marked to warrant the assumption that heredity was the probable cause of the insanity—that is to say, there had been insanity in parents or along a family line. Exceptionally marked instances of insanity in families have come under my notice, of which two may be briefly presented: Three sisters were brought to the Pennsylvania Hospital on the same day. A brother, said to have been demented, had died about two weeks previously, as was inferred, from gradual inanition and neglect. All had similar delusions of suspicion, of the operation of unseen agencies, which extended to their food, clothing, beds, the air of their rooms. The family history could not be obtained satisfactorily on account of the extreme reticence of all parties. The father had held a high official position under the government. It was an illustration of those cases of rare occurrence in which insanity is communicable in a family, or to persons closely allied in companionship and life, with few relations with the world about them. In this case one sister became insane, and gradually dominated by her superior will-power the other two. From the eccentricities of these people, their isolation and physical appearance, there had evidently been a degeneration, physical and psychic, from the normal family standard.

Recurring to the reference made to three-hundred-and-forty-seven cases, it was stated that in one-hundred-and-eighty-eight the cause in each was directly traceable to some incident in the life of the patient or to a physical deterioration or disease. There were sepsis, loss of body-weight, deterioration in the quality and constituents of the blood. The nutrition of the brain was impaired, and while many thousands of persons suffer in some degree from the same conditions and recover, insanity, which is so often only a relative condition, was but a further incident in the cases cited. In other words, insanity, or mental disorder, as in these cases, was acquired. More than one-hundred-and-forty recovered. Now, will it be said that they had acquired something they could transmit as an inheritance? If so, what was it? Is there anything material, as a bacillus of insanity, that may be received as an inheritance? That a neurotic temperament may be inherited is believed to be in accord with common observation. Such, however is the superstitious, vague sentiment existing in relation to insanity that a fear of contamination is the family skeleton. In relation to the class of cases we are now considering, it is a practice to assure relatives, when recovery does take place, that the probability of a recurrence or of the transmission as an inheritance is no greater than in those persons observed by the physician who have a pneumonia, rheumatism, or fever. Suppose the fact were otherwise, and insanity in some degree was directly transmissible by inheritance, surely man would rapidly deteriorate and degenerate until mental soundness would be of rare occurrence, and in the case of idiots and imbeciles the race would end, as it would cease to procreate.

In the procreation of children, if both parents are of exactly equal potency and not related, the expectancy will be that the physical and psychic characteristics of their children will have a close resemblance to those of the parents. Thirty-one marriages of parties not known to be related or to be descendants of relations produced two-hundred-and-seven children. None of the children was reported to have been born with any defect. (Dr. Bemiss.) If the potential power of one parent is less than that of the other (and this may be the general rule), while the expectancy would be that the offspring would partake of the stronger parent, there is no absolute rule, even here, notwithstanding the probabilities. There is a corrective process in constant operation. That nature constantly eliminates wholly or limits the influence of the weaker element is certainly true, as many families show members of very opposite degrees of psychic development. The reverse is also true, that deterioration is sometimes not wholly eradicated, but continues in an increasing degree. Two persons of marked neurotic organization may transmit their temperament to offspring in a more intensified form, and in the second or third generation, if there is no cross by which it may be by chance corrected, a neurotic heredity or predisposition is established, from which may come, with slight exciting cause, some form of mental degeneration, acute insanity, epilepsy, etc. In-breeding of temperaments, then, rather than consanguineous in-breeding, is more conductive to the development of the neuroses, to eccentricity, and insanity of the degenerative type.

In the discussion of heredity in its relation to insanity and idiocy an attempt is made to show the diversity of facts and views that exists, that there is often a personal element that enters in the preparation of statistics, that there are limitations of our knowledge ; also to formulate an expression of views or principles which are now presented as conclusions :

1. Physical characteristics, those distinguishing the human species, are transmissible as an inheritance.

2. Knowledge, genius, and culture are not an inheritance, but depend rather on influence, education, and environment. Mental receptivity is transmissible. Psychic qualities are not necessarily an inheritance, requiring favorable surroundings and circumstances for growth and development.

3. Insanity as a disease is not transmissible by inheritance, but may be acquired or evolved from a neurotic heredity as a basis.

4. A neurotic predisposition is transmissible by inheritance, but there is no absolute rule that it will be transmitted in any given case, or in any case.

5. In-breeding of neurotic temperaments is most conducive to the creation of a neurotic heredity.

6. Idiocy and imbecility may be a defect having an origin in consanguineous marriages, pre-natal conditions, accidents, arrested development, infantile meningitis, tuberculosis, and lack of potency on the part of one of the parents from unexplainable causes.

DISCUSSION.

Dr. J. Madison Taylor said that the term heredity, as used by speakers, seemed somewhat vague. Even when modified by the term inheritance, and otherwise qualified both in the papers and among neurologists generally, it is by no means clear. In estimating the scope and influence of heredity it is imperative to construe the term much more broadly, and to divide it rather into racial characteristics and tendencies, and the intermingling of these when races fuse (as here in America they do so largely), and then come down to a consideration of the peculiarities of localities and families. One thing is quite obvious from the records of Elwyn and Vineland, especially those made in the past years, that the testimony as to heredity as a factor is made vague and uncertain by many inherent difficulties, not the least of which is the unwillingness of parents to impart exact information. The only way by which this subject can be fairly judged is the very difficult one of systematically sifting all sources of testimony. Americans form a very composite race, which is becoming more so—originally of Anglo-Saxon stock in Virginia and Massachusetts, and between these an admixture of Dutch, English, and Swedes, then in Louisiana French, and now in the great Northwest millions of Slavs. In New York City alone nowadays the foreign element is tremendous, with over a half-million of Germans, four-hundred-and-fifty-thousand Irish, with Jews, Poles, Hungarians, and dwellers in Mesopotamia, "and of heathens not a few." Moreover, within the last quarter-century the character of the foreign element has changed in quality as well as in race. Being the dumping-ground of European refuse, an element of confusion enters in the physiques and characteristics of the American people of startling significance. This offscouring of the nations, representing largely abnormalities of the criminal, insane, and in various ways inferior and unstable constitutions, would seem to threaten the direst results. And yet, such is the vitality and robust vigor of American stock or climate, or social or political conditions, as statistics go to prove, that the evil tendencies that might safely be predicted from these chaotic elements do not result in the increments of criminality and insanity it would be reasonable to assume and fear. It is safe also to assume, upon adequate grounds, that the American nation is steadily improving in bodily, mental, and moral health.

Again, in judging of hereditary conditions, one must compare the tendency of physical diatheses, as of tubercle and scrofula, the toxemias, alcoholism, syphilis, and various phases of environment and education. "No man is ruined except in a line of his own propensities," and errors are always committed along the line of least resistance. When the transmission of qualities is downward and for evil the element for encouragement is never lacking. The function of heredity being the retention and transmission of tendencies, it requires suitable opportunity, and these may give a direction upward as well as downward. Qualities of heart and mind, or body and soul, may be dominant or subordinate, patent or latent, but are inevitably moulded by environment. There are evil tendencies enough throughout the realm of nature, and of sufficient strength to destroy us all, but, unless opportunity and encouragement offer, these may subside in safety. Multiply the safeguards, withdraw the encouragement, improve the environment; above all, raise the standard of self-respect, especially of sobriety, and these dormant tendencies will cease to be, as is proved about us every day. Moreover, even considering those saving peculiarities that dominate the race, and act as equating forces, such as the attraction of opposites, even here the tendency is for good to prevail. When we are better able to study and understand and control environmental conditions, the trend of heredity can certainly be checked, at least the evil trend. We shall be then left mainly with accidental and unexplainable conditions, for even now it very frequently happens that cases of insanity and idiocy occur in which it seems impossible to trace out any adequate cause.

But, lastly, the most important factor of all is evil disease and pernicious habit. Specific disease and nutritional ones, but worst of the lot, alcoholism, chronic or transient, or the pitiable instances of absolute want and insuperable physical conditions, hurtful occupations and vile dwellings: these are remediable, and yet not to be remedied.

Dr. A. W. Wilmarth stated that he is a believer in heredity, and that his opinions are based upon a long experience with the feeble-minded. The parents of the cases that are brought in are often to be found eccentric or feeble-minded themselves. Some of these feeble-minded women produce large families of defective children. A case was recalled in which a woman from Pittsburg had nine feeble-minded children. Another woman was the mother of six microcephalic idiots, and she will probably marry again as soon as her husband dies, and have more of the same kind of children. The degeneracy very often takes on a progressive type, and the marks are more evident in successive children. Two cases at Elwyn illustrate this. One child was brought by its mother, paralyzed in its legs and without the power of speech. It had, however, an intelligent look in its eyes and did not appear to be an idiot. A year later the mother presented herself with a second paralyzed and speechless child, which was an idiot, but with a different name. The father of the first child had died, and the mother had married a man who had not come to that region until after the first husband had died. They were both strong laboring men of ordinary intelligence. This showed that the degenerating tendency had increased in the woman by marriage to a man stronger than herself.

Another illustration is that of a man and his wife, in the town of Attleboro, who had a large family of degenerate children. Two of the children, a boy and a girl, were adopted into different families of respectable people to be brought up. The girl grew up feebleminded and the boy became a thief. He forged a check and ran away to the West, where he married. He had a daughter, who grew up to be a prominent woman in society and church. She had a son, who one night got up and robbed the house and disappeared. She had also a daughter, who grew up to be a shameless harlot. This family for four generations showed the evidence of heredity.

Dr. Barr called attention to the early history of Maryland, where the community was divided into three classes—namely, gentry, servants, and convicts, the first-named with more or less neurotic taint.

Among the gentry, kept absolutely distinct for years, consanguineous marriage was the rule rather than the exception, and we find a large proportion of insane and idiots up to the time of the civil war; this proportion then decreasing as the classes intermingled by marriage.

Dr. Chapin observed that confusion arises from the use and misunderstanding of terms. Inheritance and heredity have been used as synonymous terms. An inheritance is something that one receives from a parent or ancestor —something material that is transmissible—and in the case before us a disease. An heredity is a condition made up of the "physical or mental qualities or tendencies" derived from ancestors. It was pointed out that 65 per cent. of acute cases admitted to one hospital had no inheritance, although many had an heredity—they had inherited no disease from their ancestors, and had no disease they could transmit. The defects of body and mind that come to our knowledge make an impression from the mystery that surrounds all such cases; but we do not in this connection take sufficient account of the large number that show no defect, although there may be defects in the parents. We all know that parents who have consanguineous connections or who are insane have children, some of whom are every way bright and normal, while some may not be. That a neurotic predisposition or a temperament may be transmitted and intensified is established, and this is an heredity that may be a predisposing cause or soil out of which insanity may be evolved. Although conclusions are presented, the subject of heredity is one about which no agreement can be expected, as so much remains a matter of speculation. There is a limitation to human knowledge. It has been stated that the amount of insanity in Europe attributable to heredity is greater than in America. This may be due to the blending of nationalities and the influx of a vigorous physical stock. My own observations and examinations of statistics in the United States would lead to the opinion that insanity may be ascribed to heredity in about 6 per cent. of the admissions to the hospitals, and that neurotic temperaments are transmitted by heredity. Two or three generations of neurotics are sufficient to develop insanity, or, in other words, to lead to such defects that disordered physical actions will appear as a result of progressive mental degeneration. We can hardly conceive of a disease that is acquired, as insanity undoubtedly is in the majority of cases, being transmissible by inheritance. Even coincidences in families do not establish such a fact.

NEWS ITEMS.

High Death-rates in England from Influenza.—The unprecedented death-rate in England, largely due to influenza, and especially severe upon old people, has of late in London reached so high a figure as 38.5, and in Liverpool the frightful rate of 55.5 has been recorded.

The Annales d'Oculistique now appears also in an English edition, under the direction of the American editor, Dr. George T. Stevens, of New York.

HYGIENE AND TUBERCULOSIS.

BY SENECA EGBERT, A.M., M.D.,
OF PHILADELPHIA;
PROFESSOR OF HYGIENE, MEDICO-CHIRURGICAL COLLEGE.

WHEN Professor Koch first announced the discovery of the tubercle-bacillus, and showed that it was probably the exciting cause of all cases of tuberculosis, many members of the profession felt, and all hoped, that a means both of preventing and of curing this hitherto very intractable malady would soon be forthcoming; and when, later, after bacteriology had attained the dignity of a science, and the germ-theory was generally accepted, Dr. Samuel G. Dixon published the results of his work with devitalized tuberculous matter upon animals, and Koch announced some time afterward similar results upon the human system from his work with so-called tuberculin, the belief was widespread that we were on the verge of the solution of the problem. But when further trials of this new agent failed to sustain the promise of the earlier reports concerning it, the rebound of professional opinion carried us backward and probably beyond the point at which it should rest at the present time.

As for myself, I still have abundant faith that we shall ultimately be able to protect and aid humanity to a greater degree than we do now; for not only is this faith strengthened by my experience and work with Professor Dixon, both before and at the time when he first announced that he had been able to render certain animals immune to tuberculosis, but also because both the progress of science and the logic of events seem to be pointing the way in which such immunity will be eventually secured. Accordingly, I have ventured in the present article to sketch what seems to me to be a logical and scientific course by which a practical method of securing immunity from tuberculosis may be discovered, doing this not so much in a spirit of prophecy as to show that we shall probably still have to employ to the utmost all those hygienic measures that we now know to be of the greatest value in the prevention and cure of tuberculous troubles.

It will be well to note that tuberculosis, whether of pulmonary or other tissues, is a disease essentially different in a number of respects from the majority of other affections due to pathogenic organisms. It is chronic rather than acute; it destroys by slowly undermining and sapping the body's strength rather than by quickly overwhelming the vital activities with toxic bacterial products; it is not self-limited or limiting, and it especially requires a predisposing diathesis or condition of the tissues. By this last statement I do not wish to intimate that other germ-diseases are not favored by an unhealthy or abnormal state of the system, or that the rapid inoculation of large numbers of tubercle-bacilli might not produce the disease in a hitherto healthy subject; but mainly to emphasize the fact that though all dwellers in communities must be more or less liable to the reception of these specific germs, only those that have a peculiar condition of the system, whether congenital or acquired, are especially prone to the disease. For example, Bollinger has shown that one cubic centimeter of sputum from a tuberculous patient may contain from 800,000 to 960,000 tubercle-bacilli, and that the average patient throws off from 30,0000,000 to 40,000,000 of such germs per day; Dr. Prudden, of New York, has computed the number daily from a single patient as over 20,000,000; and Dr. Nuttall, of Johns Hopkins University, has demonstrated that in certain cases they may reach the enormous number of 4,000,000,000 per diem. When we consider how few, comparatively, are the tuberculous patients that take pains to destroy or disinfect their sputum, it is not hard to believe that these parasites are present in considerable numbers in our environment, even though we grant that a large percentage of those expectorated immediately experience conditions hostile to their future growth or existence. Cornet and many others have shown that the bacilli are practically always present in the dust from apartments of tuberculous patients; many gynecologists believe that the increase in cases of tuberculosis of the female organs is due to the prevalence of the germs in street-dust; and Professor Dixon and myself have observed them in considerable numbers in samples of dust from certain of our Philadelphia street-cars.

Can we doubt, then, that each one of us takes into his economy at one time or another, either from the air, drink, or food, sufficient of the germs to cause the disease, were he only in the condition necessary to its inauguration?

Moreover, the study of the malady itself seems to indicate that its progression is due not so much to the ravages of the hostile parasites as to the vital weakness of the tissues that should naturally oppose and destroy them.

Consequently, the questions that naturally arise are: What is this precedent condition of the body that is usually necessary for the incurrence of the disease? And is not the true protective immunity and cure each to be had by the securing of a change from this tuberculous predisposition to a more normal and healthful condition? Empirically, we know that this latter is just what happens whenever a patient is really cured of tuberculosis.

But what is the abnormal condition? Evidently one of faulty assimilation and abnormal tissue-metabolism. When we study the causes that predispose to pulmonary tuberculosis and other tuberculous diseases we see at once that they are those that favor faulty digestion of food, improper assimilation, deficient oxygenation of the blood, and, dependent upon all of these, the construction of weak, unstable, and unresisting tissues. And though we may seem temporarily to get good results from the use of antiseptics and other drugs, aimed with destructive or retarding intent at the germs themselves, do we not secure permanent benefits only when we employ reconstructives and use measures that will improve the digestion and the oxygenation of the blood, and that will build up new, strong, and healthy tissues instead of weak and yielding ones? Is it not for this that we carefully watch the diet, prescribe outdoor exercise, and send our patients to other climates?

Dr. T. J. McGillicuddy, in a recent article on "The Dietetic and Hygienic Treatment of Consumption,"[1] says: "To secure healthy, rich blood for the repair of diseased tissues we must have proper food and good digestion." "First, we must prepare the digestive tract and the tissues of the body to receive and assimilate the nutriment, and then we must select the most nutritious food, and so prepare it that it will be readily assimilated. Pulmonary tuberculosis is too often considered to be a local disease and treated as such. We must remember to treat the whole system, which is in a pathologic condition. The diet for the consumptive must be a scientific diet, based on a knowledge of what the different kinds of food do for the organism. This (dietetic) plan of treatment to be effective must be systematically carried out, and both physician and patient must steadfastly avoid that complete dependence on drugs which converts the wisest method of treatment into blind empiricism. There are many factors necessary for the successful treatment of consumption—rest, mental and physical, pure, dry air, gentle exercise in the sunshine—are all important; but these are as nothing if the nutrition does not receive proper attention." Nor should we forget that Pettenkofer and Voit have shown that the absorption of oxygen is determined by the nitrogenous substances comprising the tissues of the body, and that, as Fothergill says, "the presence of nitrogenized structure, and its participation in the action going on there, is a necessary condition for the manifestation of any vital energy or any chemical change in the body."

I have indicated in but a general way the state of affairs favoring tuberculosis. We are not able as yet to demonstrate exactly the condition of each organ in a person of tuberculous diathesis antecedent to the beginning of the disease itself, but I am inclined to believe that a close study of most cases will show that there are primarily imperfect digestion of proteids, abnormal hepatic action, and certain changes, both of kind and quantity, in the nitrogenous products of metabolism. In other words, the stomach and liver are more often primarily at fault than the lungs, though it may happen in some cases that the derangement of the former organs was at least partially due to faulty respiratory action or habits, bad air, imperfect oxygenation of blood, etc.

Just here I would suggest a hypothesis that appears to me, upon rather thorough investigation and inquiry, to be altogether new. May not the condition of the blood, as expressed by its coagulability, be a measure or index of the kind of tissue, as regards firmness and resisting power, which is constructed from it or by the metabolism of the body? The clotting of the blood and formation of fibrin by the antecedent production of fibrinogen, fibrinoplastin, and, possibly, a third substance, seems, at first sight, to be an extremely elaborate and unnecessarily excessive expenditure of energy on the part of Nature to provide for emergencies or conditions that are always abnormal, especially as she is prone to act simply rather than complexly, whenever possible. Why may not the principal purpose of the fibrinogen, fibrinoplastin, etc., in the blood be to assist in the construction of the active and supporting tissues of the body rather than to form fibrin solely to repair lesions of the circulatory system?

In addition, we may note that certain substances which increase the coagulability (*i. e.*, the fibrinogen, fibrinoplastin, etc.,) of the blood have been successfully used to produce temporary immunity, at least from tuberculosis and kindred diseases in susceptible animals, and that their analogues or derivatives are to be found in excess in the blood of those who are of a diathesis the opposite of that which we call scrofulous or tuberculous; while, on the other hand, substances known to decrease the blood's coagulability are very likely to be found in the circulation of those whose digestive functions are of the faulty character that predisposes to tuberculosis. For example, Dr. Dixon has shown, in an article to be mentioned later, that the substances employed by himself, Koch, Vaughan, and others, in their experimental work on this subject are all analogous and more or less closely related to the amid group of metabolic products; while we already know that such substances as nuclein, leucin, tyrosin, glycin, etc., increase the coagulability of the blood,[1] and, *per contra*, that albumoses, products of the imperfect digestion of proteids, decrease and even temporarily destroy the coagulability of the blood,[2] and everyone knows how prone tuberculous patients are to hemorrhages that are difficult to control owing to this lack of coagulability. There also seems to be a very decided relationship between the susceptibility of the various animals, including the healthy human being, and the coagulability of the blood of the respective individuals, though I must admit that there is not so much evidence at hand as I would like to have on this point.

---

[1] The Dietetic and Hygienic Gazette, November, 1894

Believing that much more can be adduced in support of the hypothesis suggested, and that it is not altogether a visionary one, I shall hope to be able to discuss it more thoroughly in a future paper. Reverting to our theme, it is essential that we should discover, if possible, the manner in which the tubercle-bacilli inaugurate the disease in a subject predisposed or susceptible to it, and the means or method whereby the predisposition or susceptibility of the whole constitution of that subject may be so altered that the germs may have no power of virulence, growth, or vitality within the system.

As to the former, we know that tuberculosis proper, that is, the formation of miliary tubercles, always begins as a coagulation-necrosis, and as we may consider from the statements and definition of Vaughan that the specific product of the tubercle-bacilli is a nuclein, which latter is one of the class of substances increasing the coagulability of the blood, it is not impossible that the following process occurs in the susceptible subject: A certain number of the bacilli finding lodgment in a certain part of the system, such as one of the alveoli of the lungs, and escaping immediate destruction, owing to the weakness of the body's resisting powers, begin to multiply and to elaborate their special product, at the same time acting as a focus of irritation, and causing a determination of leukocytes to the immediate neighborhood of their nidus. Then, as soon as the toxic product is in sufficient quantity, either acting directly or by inaugurating the reactionary production of a secondary nuclein by the leukocytes, localized and circumscribed coagulation occurs, and the enclosed leukocytes are deprived of nutrition, and are powerless further to oppose the parasites, which, still multiplying, continue the process so familiar to every pathologist. Whether the foregoing picture of the incipiency of the tuberculous process is a correct one or not, the consideration of the means for securing immunity does not depend upon it, for the latter has been shown to be based on the antecedent condition of the system rather than on the actual processes of the disease.

The fact that such investigators as Dixon, Koch, Vaughan, and others have been able to secure a condition of immunity in many susceptible animals is proof that we shall ultimately be practically successful with the great mass of human beings. To the objection that some may raise, that the conditions are not the same in the two classes of subjects, I think that, following out the thought suggested in the foregoing coagulability (?) hypothesis, it can very likely be shown that the difference, whatsoever it may be, is one of degree rather than of kind.

The first thing to be noted is the close relationship existing between the agents employed by all those who have obtained notable results, and of these agents to the nitrogenous products of normal animal metabolism. As Dixon was the first to secure anything like immunity to tuberculosis in animals—I myself having seen him do this almost if not wholly a year before Koch's announcement of his work with tuberculin—so he was the first, I believe, to show that there might be produced from cultures of the tubercle-bacilli a substance strongly resembling certain well-known nitrogenous products of metabolism, and that these latter would give, when injected into both healthy and tuberculous subjects, closely similar results to those obtained by the injection of his protective material and the practically identical tuberculin.[1] More recently Vaughan, who is using the nucleins of yeast-cells and of the spleen in this work with apparent success, has shown that the nuclein-bases yield bodies of the xanthin-group, which latter, in turn, are very closely related to the amid metabolic group of which I have just spoken.

In this connection it will not be out of place for me to call attention to Dr. Dixon's most recent and extremely interesting article on "The Possible Relationship Between the Tubercular Diathesis and Nitrogenous Metabolism,"[2] in which he not only considers this relationship much more fully and thoroughly than I could venture to do at this time, but also proposes a line of experimentation which

[2] Therapeutic Gazette, December 15, 1894.

I feel would yield valuable and interesting results if carried out. He has even gone so far as to suggest "that it might possibly be advisable to endeavor to produce a temporary condition of gout or lithemia in our tuberculous subjects, hoping thereby to possibly supply that in which the pathological tissues are deficient or to alter the condition of the tissues either in kind or degree—to change the soil, as it were, so that either the hostile pathogen could no longer find in those tissues a suitable nidus, habitat, or environment, or that the vital activities and resisting agencies of the body would be increased and strengthened sufficiently to overcome the disease-germ before it could multiply and produce its harmful effects in the body." It is also interesting, inasmuch as many now believe the therapeutic efficacy of cod-liver oil to be dependent upon its alkaloids, to note that three of the latter closely resemble urea in structure and formula, and that the other three are closely related to a combination of the glycerin and amidogen radicles.

By this I do not mean to create the impression, any more than does Dr. Dixon, that by the use of the amids results or reactions are to be obtained exactly similar to those due to tuberculin ; for the latter, being a specific product of the bacilli, most probably causes a specific action in those cells and tissues that react to it, just as the diphtheria-antitoxin of Behring and Roux is produced only by the influence of the peculiar product of the diphtheric bacilli.

With this evidence, and granting that the opinion expressed in the earlier part of the paper, that in most cases of predisposition there is "primarily imperfect digestion of proteids, abnormal hepatic action, and certain changes of kind and quantity in the nitrogenous products of metabolism," is well founded, it certainly is not difficult to surmise a connection between these various amid substances, all more or less closely related, and the metabolic activities and functions concerned in the production of a predisposing diathesis.

We have as evidence of the manner in which the inoculation of these toxins, nucleins, etc., secures or induces protection the work of Buchner, Nuttall, Vaughan, McClintock, and others, which goes to show that the inoculated substances incite or stimulate the leukocytes, and possibly other active cells of the body, to the elaboration and secretion into the blood-serum of secondary nucleins, antitoxins, alexins—call them what we will—which are not only germicidal but also antagonistic and, as it were, antidotal to the bacterial poisons. This is the principle underlying the new serum-therapy, which is apparently proving itself so successful in the treatment of diphtheria, tetanus, etc., and we may thus the more readily accept the reports of Viquerat's success in gaining immunity from tuberculosis by the use of the serum of asses, though even in his case it will doubtless be found that, like Dixon and Koch, he has for his primary agent the toxin or nuclein of the tubercle-bacilli.

From this point we may take one step further, to inquire into the physical nature and structure of the cells secreting the protecting alexin, and then we must wait for light to be shed in the future upon the still hidden processes of the body. Bütschli has arrived at the conclusion that the framework of protoplasm must be "a fluid substance insoluble in water," and that "it must be formed by a body which has arisen from a combination of albuminoid and fatty acid molecules ;" while Reinke believes that this so-called *plastin* is a "combination of albumin and *nuclein*, possibly further accompanied by a number of molecules of a fatty acid belonging to the stearic or oleic acid series."[1] The connection between this and what has already been said about protective nucleins (alexins), and also in relation to my hypothesis regarding the constructive functions and processes of the body, must be obvious to everyone.

In the foregoing I have tried to collate and arrange logically the knowledge that we already possess concerning this important question, and though it is difficult to place the facts in their proper order, and the proofs of some of them may not be so positive as we should like them to be, I trust that I have made clear the points in question, viz. : That a predisposing condition is essential to the inception of the disease ; that immunity has been produced by a number of investigators in susceptible animals ; that the substances thus successfully used are very analogous one to another ; that they probably act by stimulating the leukocytes and other active cells of the body to the production and secretion into the blood-serum of nucleins or alexins which tend to neutralize the bacterial poisons, and that these agents, favoring immunity, also increase the coagulability of the blood, which being decreased in the tuberculous condition and for other reasons given, may possibly be important as an index of the formative or constructive powers and processes of the system. I also hope the paper may serve to indicate the direction in which we can reasonably look for further advances in this important matter. But, though there is fair promise for future success in the protection of humanity against tuberculosis, we must not forget that whether this be attained through the inoculation of tuberculin, nucleins, serum, amids, or, possibly, other substances that will increase the formative and constructive powers of the blood and tissues, there wil always be prime necessity for the additional and assiduous employment of those broad hygienic measures, such as exercise and life in pure air, respiratory gymnastics, freedom from mental worry or fatigue, improvement in gastric and hepatic digestion, etc.; and I do not go too far, perhaps, in saying that without these latter the use of inoculatory methods alone will probably prove illusory and far from satisfactory. In other words, it is the predisposition rather than the attacking pathogen that needs attention, for with the former wanting the latter will be impotent for evil under all ordinary conditions. By this I would not deprecate the use of protective inoculations in all predisposed or incipient cases as soon as the proper substances and the means of using them shall be surely known; but simply advise against the error of placing sole reliance upon them to the exclusion of what must always be of paramount importance.

ANESTHETICS IN THE EARLY AND MIDDLE AGES.[1]

By R. HARCOURT ANDERSON, M.D.,
OF NEW YORK.

AN anesthetic may be defined at the present time as any agent that will produce anesthesia, which condition, according to Wood, is loss of consciousness produced or accompanied by loss of sensibility or diminished muscular action. As to how this is brought about, the various theories are too numerous to entertain here. It will suffice to say that the action of such an agent is undoubtedly through the nerve-centers. A few of the plausible theories are: Partial arrest of oxidation; precedent physical changes in the blood, due to cerebral anemia (like sleep); the well-known theory of Claude Bernard, that it is produced by semi-coagulation of the nervous protoplasm.

Many, if not all, anesthetics have the power of dissolving the red blood-corpuscles, and as Ludimer Herman stated in 1866 that protagon, which constitutes the stroma of the red blood-discs, is an important constituent of the nerve-centers, and as death would necessarily occur before this could be dissolved out of the nerve-centers, *i. e.*, before it could be dissolved out of the red corpuscles, the evidence is that no extensive destruction of the latter bodies can occur from the action of an anesthetic and the subject survive. It is interesting in relation to our modern information on the subject of ptomains and toxemia that Herman states that bile-acids also dissolve protagon, and experiments made by him seemingly indicate that they have anesthetic properties. This ingenious theory of Herman has not, however, been entirely proved.

Regarding Claude Bernard's theory, from a conclusive standpoint, we can only apply the term "assumptive" to it. It seems that the lungs are simply avenues through which the anesthetic passes on its way to the central nervous system by means of the blood, and that, other things being equal, if the same condition is produced through other avenues than the lungs the condition will be the same so far as surgical utility is concerned.

In the hurry and rush of this nineteenth century we are continually losing sight of agents that have been valuable in more senses than one to our predecessors. Among the most important of the drugs used for the production of anesthesia by the ancients is atropa mandragora or mandrake, which somewhat resembles the atropa belladonna of the present day, but this drug is not identical with our mandrake. It has been fully described by Dioscorides, and later by Pliny, the former stating that wine of mandrake was used in cases of amputation or of cautery, to prevent pain, and speaks of the pure juice used in the form of a suppository to induce sleep. Pliny says: "Mandrake is taken against serpents, and before cutting and puncture, lest they be felt. Sometimes the smell is sufficient." According to Apuleius, half an ounce of the wine would render a person insensible even to the pain of amputation. This preparation was used extensively by the Grecian physicians, and known to them as "morion." According to Lyman, the Biblical expression found in the 15th chapter of Mark, verse 23, "Wine mingled with myrrh" (which was offered according to the custom by pitying souls of that day to Christ on the cross) was unquestionably the same anesthetic wine.

That the ancients also understood the use of combining drugs is shown by the following quotation from Dioscorides, mentioning the method of preparing the sleeping apple: "Opium, mandragora, juice of water hemlock, and the seeds of hyoscyamus and musk; the apple (so he states) when repeatedly smelt softens down and binds the eyes in sleep." The juice of the root of fenugreek or trigonella fœnum was applied to the nostril to bring the patient back to consciousness. He also says physicians used this when they were about to burn or cut. Galen refers to its power to paralyze sensation and motion. According to Paulus Ægineta, Isodorus writes: "The wine of the drug of the root is given to those about to go under an operation that, being asleep, they may feel no pain." Serapion says that it is administered as an anesthetic prior to operation. Again, Theodorica, the famous surgeon of the school of Bologna, was in the habit of using a combination of hyoscyamus, hemlock, lettuce, ivy, mandragora, belladonna, and opium. This was administered upon a sponge previously saturated with hot water, used before operations, the patient being aroused by instilling the juice of rue in the ear. We can still see traces of this practice of ear-instillation in Shakespeare's death of King Hamlet. Mandragora was also used to avoid the pains of labor.

---

[1] Read before the New York County Medical Association November 19, 1894.

Our predecessors were enabled to bring the preparation of so-called anesthetic drugs to greater perfection after the introduction of the process of distillation by the Moslems, and William Bullein, a celebrated anesthetist, who lived in the reign of Henry VIII, described the preparation of his anesthetic mixture as "the juices of a certain herb pressed forth and kept in a closed earthen vessel, according to art (probably distillation), bringeth deep sleep and casteth man into a trance or deep terrible sleep—until he shall be cut of the stone."

In the writings of the poets we see innumerable references to anesthetic drugs. Shakespeare says:

CLEOPATRA: "Give me to drink mandragora,
That I might sleep out this great gap of time,
. . . . . .
My Antony is away."
Antony and Cleopatra—Act I, Scene 5.

IAGO: "Not poppy, nor mandragora,
Nor all the drowsy syrups of the world
Shall ever medicine thee to that sweet sleep
Which thou owdst yesterday."
Othello—Act III, Scene 3.

and in more modern times Mrs. Browning says:

"Have the pigmies made you drunken,
Bathing in mandragora?"
Dead Pan, II.

And finally a French writer says, "Like a patient sent to sleep with mandragora, I do not feel my disease."

Sir B. W. Richardson, of England, about 1873 demonstrated unquestionably the anesthetic properties of mandragora.

Wood says, "I know by experiment that vapor of alcohol is capable of producing the stupor known as anesthesia, and, further, that this may be deepened into death accompanied by the phenomena of fatal ether-narcosis." About the twelfth century Albertus Magnus wrote about a liquid which he called aqua ardens, which was obtained by distillation from a mixture of the following: Red wine, quicklime, common salt, and green figs. By dissolving this we undoubtedly would get a concentrated alcohol with perhaps a little more than a trace of ether. This aqua ardens was used for the production of anesthesia.

The Chinese used cannabis indica or a drug closely allied to it for the prevention of pain during the operation of acupuncture.

Herodotus states that in early times anesthesia was produced by inhalation of bhang or hasheesh, even before the use of mandragora, and it was used for the express purpose of operative procedure. He also states that the Greeks were familiar with the use of the drug. Literature on the subject also shows that the Scythians were in the habit of producing intoxication by means of inhalation of the vapor of hemp, and experiments made by Prof. Wood, of Philadelphia, on himself, show undoubtedly that this drug will produce unconsciousness for a certain time.

It is probably well known that Dr. Esdaile (according to Mr. James Braid) performed upward of three-hundred capital operations in India, many of them of the most terrible nature, without pain, using hypnotism as an anesthetic; and in 1829, Cloquet ablated the breast of a woman without pain, while in a hypnotic state. A similar process was known among the early Greeks, "touching them with his hands, he (the physician) quickly makes them whole." And we see here the connection in the laying on of hands (in some of the ceremonies) of the Greek and Latin Churches, notably the extreme unction of the Roman Catholics. Another means of producing anesthesia was that of the ancient Assyrians, who alleviated and even entirely prevented pain incident to circumcision by compressing the veins in the neck, and also probably the carotids, producing cerebral anesthesia.

Comerarius, writing A. D. 1625, says that anesthesia may be produced by means of a gas obtained by treating certain drugs in vessels.

Boerhaave, in one of his Aphorisms, shows the use made of volatile oils according to this prescription:

R.—Oil of cinnamon	gtt ij.
Oil of cloves	gt j.
Citron peel	gr. ij.
Sugar	ʒij

M. et adde red coral, prepared, ʒj; pure opium, gr. ij. Mix for two doses, one to be taken an hour before the operation, and the other fifteen minutes before, if the patient be awake.

Guillaume de Sallaste Du Bartos writes in 1544:

"Even as a surgeon, minding off to cut,
Some useless limb, before in use he put
His violent engines on the vicious member,
Bringeth his patient in a senseless slumber,
And griefless then (guided by use and art)
To save the whole, cuts off the infected part"

Boccaccio, in the story of Dioneus, gives an account of the anesthetic mixture of Surgeon Mazzeo de la Montagnos.

Moore, of England, 1784, tried to produce the effect of anesthesia by means of clamp-like devices which pressed on the nerve-stems of the extremities about to be operated upon, and, as every one is well aware, in 1799, Sir Humphry Davy discovered the intoxicating effects of nitrous-oxid gas, which led to the discovery and use of the modern alcoholic series of anesthetics.

INTRA-ABDOMINAL SHORTENING OF THE ROUND LIGAMENTS FOR RETRO-DISPLACEMENTS OF THE UTERUS.

BY MATTHEW D. MANN, A.M., M.D.,

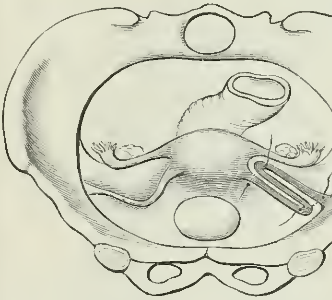
PROFESSOR OF OBSTETRICS AND GYNECOLOGY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO.

THE treatment of posterior displacements of the uterus by operative procedure has come to be recognized as, under certain conditions, fully justifiable. The plans followed by most operators in this country may be grouped under two heads:

First. Those having for their object the shortening of the round ligaments outside of the abdomen (Alexander's operation and its modifications); and, secondly, those in which either the uterus is fixed to the abdominal wall, or the round ligaments are shortened between the uterus and the sides of the pelvis within the abdominal cavity.

Of Alexander's operation I have nothing to say. It has its advocates, while there are many who unhesitatingly condemn it. My experience has not been sufficient to allow me to give an unqualified judgment. I, therefore, refrain from giving any. As regards ventral fixation, it has always seemed to me to induce an unphysiologic condition. The uterus is not normally attached to the abdominal wall, and it is hard to understand how attachments made in this way can take the place of the natural supports. I have, therefore, always preferred an operation that accomplishes the shortening of the round ligaments from within. A number of plans have been suggested, notably those of Drs. Polk and Wiley. I have no new plan to suggest, but simply a modification of one of the old ones. It is not necessary for me to review the various steps by which I arrived at the procedure that I now follow, but I shall at once describe it:

First. A moderate-sized opening is made in the abdominal wall. Any adhesions that may bind down the uterus are broken up, and diseases of the tubes or ovaries that may demand attention are properly treated, either by the conservative method or the diseased organs are removed. The patient is then placed in the Trendelenburg position, a large, flat sponge spread over the intestines, and the uterus pulled up as near the abdominal wound as possible. By pulling the uterus to one side the round ligament on the opposite side is put more or less upon the stretch, and made distinctly visible. The ligament is then seized with two long-handled hemostatic forceps, the points of seizure dividing the ligament as nearly as possible into three equal portions. A little lapping over of the parts and comparing will tell whether the division is equal or not.



The next step consists in passing a needle threaded with silkworm-gut through the loop nearest to the abdominal wall, the needle being then made to pass under the point where the round ligament is inserted into the uterus, a considerable quantity of uterine tissue being included in the suture. The hemostatic is then removed, and the loop of ligament tied to the uterus. It is necessary when the ligature is first pulled that it should not be drawn too tightly; but the second half of the knot should be tied as tightly as possible in order to prevent slipping. The ordinary square knot is the one used. The ends of the silkworm-gut are cut off quite close to the knot. A second stitch is passed through the ligament just as it leaves the abdominal wall, and then through the loop in that portion of the ligament nearest to the uterus. The ligature is tied and cut as before. In this way the ligament is doubled on itself twice, and three thicknesses of round ligament are stretched between the sides of the pelvis and the front wall of the uterus. The same thing being done on the opposite side, the wound is closed as usual. Reference to the cut will make it clear.

The material used for ligature may be silkworm-gut, as I have indicated, or ordinary silk. I prefer the former, but have sometimes used silk. I have performed the operation many times—upward of thirty—and have never seen any harm resulting from the silkworm-gut. It seems to me better to use a ligature that will not be absorbed, and to trust to its sustaining power, rather than to use an absorbable ligature and trust to adhesions alone. The adhesions will, I believe, eventually be absorbed and the end of the operation defeated.

The point at which the needle should pierce the ligament is of some importance. The artery runs just below the ligament, and if it be included in the ligature harm might result. By penetrating the ligament so as to include about two-thirds in the grasp of the needle the artery will certainly be avoided.

The results of this operation in my hands have been eminently satisfactory. I have seen but one failure, and in this the failure was only partial, there being a certain amount of prolapse and very slight retroversion. The uterus was very large and heavy. It was one of my earlier cases, and the operation was not performed exactly as I have described. The uterus was easily held up by a pessary, and the patient is perfectly comfortable, though, unfortunately, compelled to wear the support.

The advantages that I claim for the operation are, in the first place, that it cannot primarily fail. One is perfectly certain of finding the ligaments and of shortening them to any required degree. Secondly, the uterus is left in its natural position, and supported by its normal ligaments. There are no loops or holes for intestines to enter, thus causing intestinal obstruction. Should pregnancy occur the uterus is left free to move and to rise, as may be required. By the use of a non-absorbable ligature the result is likely to be permanent. The only way failure can result is through the cutting out of the ligature, and if it is not tied too tightly this is very unlikely to occur.

The indications are as follows:

1. Whenever the lower portion of the abdomen is opened, in the case of retro-displacement, for any object whatsoever.

2. When the retroverted uterus is adherent.

3. When there is coincident disease of the appendages.

4. In simple cases when a pessary does not accomplish the desired result, and when the operator prefers this operation of Alexander's.

The objections to the operation are that it opens the abdomen for what may seem a comparatively unimportant disease, the dangers being those inherent to any celiotomy. The actual dangers to life are, in my opinion, so trifling as to be scarcely worthy of notice. Nor are they greater, I believe, than in Alexander's operation. There are cases recorded in which Alexander's operation has been followed by peritonitis and death,[1] and in many instances the peritoneal sac has been opened in peeling it from the ligament. A properly performed celiotomy is as little dangerous as almost any operation that is performed under an anesthetic.

The real objection to my mind is the presence of a wound in the abdominal wall. That this is a real objection cannot be denied. The dangers of abscess, of ventral hernia, and adhesions of intestines causing obstruction are very real, and I must confess to having met with all of them more than once. Their infrequency, however, when the operation is carefully performed, so far diminishes the risk that they ought not to count very heavily. If, for instance, we compare the operation with Alexander's operation, there is an equal danger of suppuration, almost equal danger of peritonitis, and unquestionably, if Alexander's operation is performed by opening up the inguinal canals, there is a danger of hernia, a fact that has been observed.

I do not wish to compare this operation with Alexander's operation, but merely to show that it is not in reality much more dangerous. When the abdomen has to be opened these objections all vanish, and it remains to my mind the best operation yet proposed for sustaining the uterus in its normal position. The tendency in these days is to give up the abdominal incision, making all operations *per vaginam*. A great objection to this mode of operating is that with it, as yet, no thoroughly reliable method of fastening up the retroverted uterus has been invented. Dr. Polk, I know, has reported some cases in which a suture was passed through a partial abdominal incision into the fundus. It seems to me that this cannot be relied upon for certain success. Adhesions formed in this way will, I am sure, soon be absorbed, and the uterus be allowed to drop back as badly as before. Doubtless some method will be invented to overcome this difficulty; but, until it is done the advantages seem to me to lie with celiotomy when retroversion exists.

---

[1] British Gyn. Journ., November, 1894, vol. x, p. 408.

It may be objected that the amount of shortening of the ligaments by this plan will be too great. I can only answer that I have not found it so. The ligaments in these cases are always greatly relaxed. Moreover, they are elastic, and will bear the necessary stretching very well.

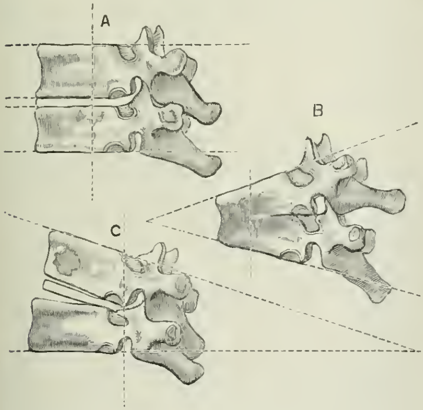
In conclusion, I can only ask that the operation be given the test of experience. I am sure it will be found easy, certain, and effective.

AN ORIGINAL METHOD AND APPARATUS FOR APPLYING PLASTER-OF-PARIS JACKETS IN POTT'S DISEASE.[1]

BY R. TUNSTALL TAYLOR, M.D.,
OF BALTIMORE.

MY aims in this apparatus have been, first, to put the patient in as comfortable a position as possible, in which, at the same time, he can keep reasonably quiet while the jacket is being applied; and, secondly, that the position shall be such as to elevate the ribs and cause a backward bending of the spine, producing a certain degree of lordosis, involving both the dorsal and lumbar regions. This is done in order that the center of gravity of the spine may be thrown further backward and the superincumbent weight be removed, more or less, from the diseased body or bodies of the vertebræ, to the healthy transverse and articular processes (Fig. 1, A, B, and C).

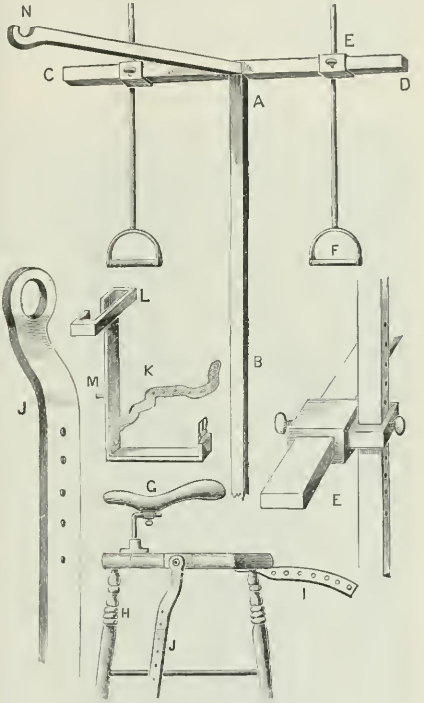
FIG. 1.



Diagrams showing:
(A) Normal position of adjacent vertebræ;
(B) Falling forward of the vertebral bodies in caries of the spine;
(C) The aim of treatment of Pott's disease by means of spinal extension in its true sense;
—— —— —— = The planes of the vertebral bodies;
– – – – – – – = The line of the center of gravity and of the superincumbent weight.

The first of the aims, a comfortable seat, is met by utilizing a stool (Fig. 2, H), on which is fastened a bicycle-seat (G), taking up no space laterally.

FIG. 2.



Diagrams showing the details in the mechanism of the Taylor plaster-jacket stool. (See text.)

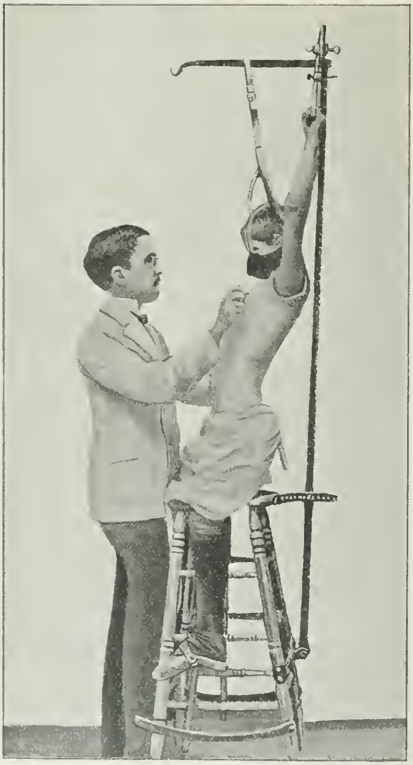
The feet are supported on stirrups (K), made adjustable by a sliding-joint and pin (L and M). This sliding-joint works on a rigid rod (J), which in turn can be moved through an antero-posterior arc, so that the legs of the patient can be put in any desired position, by means of a bolt which passes through the arc and rod.

The second aim, that of the production of lordosis, is met by having an upright (A B), which extends some distance above and behind the patient's head, and has a cross-bar (C D) on its top, making a T. From this cross-bar descend rods (E F), on which are handles (F). These rods are made adjustable at the cross-bar for long or short arms, broad or narrow shoulders, by a double joint (E), by which they can be moved up or down, and also sideways. The central upright is attached near the bottom of the stool behind, by a joint, which allows motion in an antero-posterior direction, regulated by a set-pin and arc (I) which project back from the seat. Thus it will be seen, when the patient grasps the handles, his arms being stretched upward and the central upright is moved backward, the pelvis being more or less fixed, the result is that the ribs are raised and the shoulders and spine are curved backward. (Fig. 3.)

---

[1] Paper read and the apparatus shown to the Johns Hopkins Hospital Clinical Society, January 20, 1895.

FIG. 3.



The application of the jacket on the stool.

Then the jacket can be easily applied and carried higher up and closer over the sternum than is possible by other methods, an end which we wish to gain in all jackets for Pott's disease, thereby preventing, as far as possible, the forward bending of the spine, and with it compression of the diseased vertebral bodies.

Thus far the advantages presented by this apparatus seem to me to be:

1. The jacket thus applied fixes the spine in the most advantageous position for lessening the tendency for the production of deformity, and when a plaster jacket is indicated for any reason in preference to a steel back-brace, this method I have found the most efficient in applying it.

2. The rapidity and ease with which a jacket may be applied, an advantage of no small moment in a crowded out-patient plaster-room. These jackets require, as a rule, no trimming at the crease of the groin in front or in the axillæ, notwithstanding that they are carried high up on the sternum.

3. It seems applicable to dorsal and lumbar caries, especially the former. In high dorsal caries (*i. e.*, in disease above the seventh dorsal) the jacket should be supplemented by a "head-support."

4. It seems comfortable to the patient, as the thorax is well supported and the superincumbent weight is removed from the diseased vertebral bodies to the healthy articular processes and hips.

5. It is not an expensive apparatus.

I wish especially to emphasize the importance of the rigid supports for the hands and feet in this apparatus, as swinging ones were tried and found unsatisfactory.

Certain precautions are necessary for the successful application of a plaster jacket by this method:

1. To avoid fatigue to the patient, the arms need not be elevated after the handle-rods and uprights are adjusted, until just as the plaster rollers are to be applied, which, although but a question of a few minutes, will be found a point worth noting clinically.

2. To insure a close-fitting jacket over the pelvis, it is well to have the legs fully extended on the stirrups.

3. To avoid breaking up adhesions that may have already formed in partly ankylosed spines, it is not advisable to carry the backward bending to a point where discomfort is produced, which should be our guide in fixing such cases.

Finally, in many cases to apply a comfortable and successful jacket, a forward projecting-rod is fastened to the central upright (Fig. 2, N), from which a head-sling extension can be used to insure additional support and steady further the patient when restless, nervous, or in pain.

2000 MARYLAND AVENUE.

The Monatschrift für Geburtshülfe und Gynaekologie is a new publication under the editorial charge of Prof. Martin, of Berlin, and Prof. Sänger, of Leipsic.

IS THIS THE NINETEENTH CENTURY?

BY RICHARD SLEE, M.D.,
LATE PATHOLOGIST TO THE NORWEGIAN HOSPITAL; PATHOLOGIST TO THE CENTRAL THROAT HOSPITAL AND POLYCLINIC DISPENSARY; ASSISTANT PATHOLOGIST TO THE METHODIST EPISCOPAL HOSPITAL, AND ASSISTANT TO THE DEPARTMENT OF PHYSIOLOGY, HOAGLAND LABORATORY, BROOKLYN, NEW YORK.

THE interesting article on physio-medicalism, by Dr. Nichols, and the bright and overflowing editorial in lieu of a review on the "Essentials of Homeopathic Therapeutics," in recent numbers of THE MEDICAL NEWS, have tempted me to bring to the notice of the profession a school of medicine with which few of my co-workers are probably familiar. Perhaps the quickest method of explaining will be to report several cases bearing on the treatment.

CASE I.—I was recently called to attend a young man who had an incised wound on the dorsum of the foot from which there was persistent arterial hemorrhage. This was on Thursday, the wound having been received on the previous Monday; the young man's condition was, of course, bordering on *extremis*. A few stitches at once controlled the hemorrhage, and he made an excellent recovery.

I was not surprised to find that everything from Mustang Liniment down to cobwebs had been used in the endeavor to control the bleeding before calling me in (though my office was only a few rods from the boy's home), but I was simply astounded to find that among the numerous things done was the calling in of a "pow-wow doctor."

Pow-wow is the term given to a form of incantation that I find very much in vogue among the native population. Let me also add that these "doctors" are said to accept pay for their services. The possessor of the charm, whether man or woman, comes by it through several channels: a man who is the owner of a charm may tell it to a woman, or a woman may tell it to a man, but should either chance to tell one of the same sex—*presto*, change!—the one told becomes the possessor, and the narrator is "out in the cold!" Charms are, therefore, well guarded. When a pow-wow doctor is about to shuffle off this mortal coil there is great scampering to see who can secure the charm, as it possesses more potency when one becomes possessor in this way. As I am an outsider, so to speak, and a to-be-expected opponent of this form of medical practice, I have found it difficult to gather many data regarding it; but from a very few skeptics I have been able to glean a few facts. As a rule, a pow-wow doctor is a specialist, one pow-wowing for fits, another for worms, another for hemorrhage, the next for rickets, and so on. With all these experts in their several branches, I, of course, suffer just as much as my young brethren do in the city, for I am only a general physician. I have not been able to learn the secrets of any of the charms, but I have found that they consist in repeating certain portions of Holy Writ in such a manner as to be unintelligible to the hearers, at the same time performing certain impressive ceremonies. In the case of hemorrhage the pow-wow doctor filled a large shovel with live coals, and marched round the sufferer's bed, repeating his pow-wow. This he did three times, the number three playing an important part in this line of treatment. All well-behaved hemorrhages should cease after this; but, as in this case, the hemorrhage forgot its manners, and the boy fainted from loss of blood, I was sent for, and was enabled to demonstrate the superiority of a couple of properly applied sutures over all the pow-wows they could command. In place of being thankful to me for saving the boy's life, I am sure they detest me for upsetting their idol.

CASE II.—Another patient whom a number of physicians saw, and, according to the parents, could not help, was that of a rachitic child, who was treated by an old woman pow-wow, and cured by the following simple line of procedure: The child's back was shaved with a sharp razor to cut off the *heads of the worms* which were causing the disease (pathologists should make a note of this), and the parts were then anointed with some oil. The *séance* was thrice repeated, and a complete cure was the result.

CASE III.—I was called to see a child who was "*liver grow'd*"—an anatomic or pathologic condition of which I must confess to be ignorant in spite of a rather large post-mortem experience. The treatment previously to my being called in consisted in passing the child through a horse-collar, then around a table-leg, not forgetting the charm to be spoken during the act. Calomel, gr. ii, cured this critical condition in twelve hours, and I made another enemy.

I could go on indefinitely, relating the histories of similar cases; but these will illustrate my school of medicine, which is to-day flourishing within one-hundred miles of Philadelphia and New York. Among what class of people and where? Not in the backwoods, but in a thickly settled and prosperous district, and among people of moderate education. The pow-wow referred to as treating the patient in Case I was a man of some attainments, the father of the boy being the mainstay of the village (Methodist Episcopal) church, who, when he prays and exhorts does so in such an audible tone that in summer I am constrained to take to the woods. I beg not to be understood as scoffing at religion, as I am a firm believer in it; but I somehow cannot expand my limited intellect to understand a synchronous belief in the two forms of faith.

This question, however, has a serious side, and one that I think the profession should join in endeavoring to improve. Coming from another State, I was required to take an exhaustive examination before being allowed to practise. The reason for all this red-tape I cannot see, as apparently my duty to the county and its own duty to me end with my paying my dollar for the privilege of registering. We have no Board of Health, no registration of deaths or of births, at least none for the doctor to sign; in fact, it makes not the slightest difference whether there has been a physician in attendance or not. It frequently happens when an old person is taken sick that a doctor may not be called in, or not more than once or twice, because the patient is old enough to die, and there is no use in spending good money upon him. Fatal accidents happen which in the city would at least call for an inquest, but here none is held, no matter what are the circumstances. (To be correct I recall one, which the District Attorney had made in a case of murder.) It is thought sufficient to call in the undertaker and give the victim a proper burial. Illegitimate births are of frequent occurrence, nothing being thought of them if the constable succeeds in marrying the parents a few days before the child is born; if not, the mother is simply spoken of as having been unlucky, and has no stain in the eyes of future suitors for her hand.

The district flourishes in churches, so many in fact that they all have small attendance and the ministers are half-starved. The country about is a famous summer resort, and is filled with thousands of educated visitors each year. I have not made the colors so dark as I might. I ask the profession if some legislative action should not be taken with a view to requiring at least the registration of births and deaths and the investigation of all fatal cases in which a physician has not been in attendance?

BACTERIOLOGIC REPORT.

A BACTERIOLOGIC STUDY OF OYSTERS, WITH SPECIAL REFERENCE TO THEM AS A SOURCE OF TYPHOID INFECTION.

BY CHARLES J. FOOTE,
DEMONSTRATOR OF BACTERIOLOGY IN THE MEDICAL DEPARTMENT OF YALE UNIVERSITY.

AT the suggestion of Dr. C. A. Lindsley, Secretary of the Connecticut State Board of Health, I have made some bacteriologic experiments with oysters and with the water in which they grow, in order to determine how far the bacteriologic evidence supports the idea that typhoid fever may be communicated by oysters.

The conditions favoring the communication of typhoid fever by oysters require that the Bacillus typhi abdominalis should live a few hours at least in the water in which the oysters grow, and that, having been received between the shells of the oyster, it should live in the substance or juices of the oyster until such a time as this is eaten. In this locality this time would be from a few hours to four or five days, as it is the custom to "drink" the oysters in the river after bringing them in from the sound, for a few hours or days before opening them, in order to clean them, lessen their salty taste, and fatten them.

The work of other investigators on the vitality of the B. typhi abdominalis in salt water is not quite applicable to the instance under discussion, inasmuch as the temperature of the water is not given nor the amount of salt; and indeed, in some instances, the experiments were made with a sterile salt-solution. Freytag found that the B. typhi abdominalis would live in concentrated salt-solution five months.[1] Giaxa detected it in unsterilized sea-water after nine days from the date of infection, in sterilized water after twenty-five days.[2]

My experiments were made to find how long the B. typhi abdominalis would live in water having the same percentage of salt, the same temperature, and the same bacteria as the water in which the oysters were planted.

On December 20th a liter of water was taken from the river X, at low tide, in a sterilized flask directly over the oyster-beds. The flask was carried immediately to the laboratory, and ten c.c. of a bouillon-culture of the B. typhi abdominalis were emptied into it. The flask was then put in a wooden box outside of the window of the laboratory. Thus the temperature of the water approximated at least that of the river. The mean daily temperature of the weather during the experiment was taken from the weather-reports, and was as follows:

December 21st, 36° F.; 22d, 42° F.; 23d, 24° F.; 24th, 24° F.; 25th, 38° F.; 26th, 24° F.; 27th, 25° F.; 28th, 10° F.; 29th, 9° F.; 30th, 18° F.; 31st, 24° F.

For the first few days the water was not frozen, protected as it was in a wooden box, but during the last four days of the experiment there was a large cake of ice in the flask, and on December 30th the water was completely frozen and the flask cracked.

The last plate from the ice, made on December 31st, shows the vitality of the B. typhi abdominalis in frozen brackish water.

Agar plates were made from the flask of water on December 23d, December 27th, and December 31st. The plates were kept at 37° C. Check-plates were made also from a bottle of water from the river X, which was taken at the same time as the other sample, and was not infected with the B. typhi abdominalis. In every case $\frac{1}{10}$ c.c. of water was added to each plate, and in all cases in which I have stated that the B. typhi abdominalis was present cultures were made, from one or more colonies of each agar plate, on potato and in litmus milk, thus verifying the diagnosis.

The results were as follows:

Number of Colonies in $\frac{1}{10}$ c.c. of Water.

Plate of 23d, of infected water,	Innumerable cols. of B. typh. abd.
Check-plate of non-infected water,	2 or 3 cols., none resembling B. typh.
Plate of 27th, of infected water,	Innumerable cols. of B. typh. abd.
Plate of 31st, of infected water,	Innumerable cols. of B. typh. abd.

An estimation of the chlorin in the infected water was made, and there was found to be 0.1 per cent. chlorin or 0.15 per cent. salt.[3]

---

[1] Zeitschrift für Hygiene, 1890.

[2] Zeitschrift für Hygiene, Bd. vi, p. 162.

[3] For this analysis I am indebted to Prof. H. E. Smith, of the Yale Medical School.

On January 15th two more samples of water were taken from the river X in sterilized liter flasks.[1] To one of the samples 10 c.c. of a bouillon-culture of the B. typhi abdominalis were added; the other sample was used to make check-plates.

The flasks were kept at the temperature of the laboratory, as it was desirable to prolong the experiments, and it was feared that if exposed to the outdoor temperature the water would freeze and the flasks crack. The temperature of the laboratory during the experiment ranged from 60° F. to 70° F.

Plates were made at the dates recorded, with the following results.

Water of river X—second sample—$\frac{1}{10}$ c.c. in each plate—water infected on January 15th.

Number of Colonies in $\frac{1}{10}$ c.c.

	Water infected with B. typh. abd.	Non-infected water.
Plates of Jan. 16th,	Innumerable cols. of B. typh. abd.	4 cols; none of B. typh. abd.
Plates of Jan. 18th,	Innumerable cols. of B. typh. abd.	4 cols.; none of B. typh. abd.
Plates of Jan. 21st,	Innumerable cols. of B. typh. abd.	5 cols; none of B. typh. abd.
Plates of Jan. 23d,	Innumerable cols. of B. typh. abd.	2 cols.; none of B. typb. abd.
Plates of Jan. 28th,	130 cols. of B. typh. abd.	3 cols.; none of B. typh. abd.
Plates of Feb. 1st,	About 10 cols. of B. typh. abd.; many other kinds growing on plate.	Sterile.
Plates of Feb. 5th,	B. typh. abd. not discovered; plate overgrown with other kinds of bacteria.	

We may conclude from these experiments that even in extremely cold weather the B. typhi abdominalis will live in unsterilized salt or brackish water eight days at least, while in warmer water it rapidly diminishes in number after the first week, and cannot be detected in the water after three weeks.

To determine whether the B. typhi abdominalis will live and multiply in oysters, it is necessary, as a preliminary step, to find out what bacteria, if any, are found in oysters, and whether any of them resemble the B. typhi abdominalis. To determine this point some oysters were taken from the river X on November 27th, at low tide, scrubbed in city water, rinsed with sterilized water, dried on a clean towel, and opened with a sterilized knife.

The juice surrounding the oyster was drawn off with a sterilized pipet, and gelatin plates were made, each one containing one drop of the juice. Tubes of Paretti's solution were also infected with five drops each of oyster-juice. A sterilized platinum loop was plunged into the liver and stomach, twisted around, drawn out and rubbed over slant tubes of agar.

The agar tubes and Paretti's solution were incubated at 37° C., the gelatin plates at about 22° C.

The oysters used in this experiment were numbered 1, 2, 3, 4, and 5.

The results were as follows:

Tubes of Paretti's Solution.

Oyster 1	Cloudy.
" 2	"
" 3	"
" 4	"
" 5	"

Gelatin plates were made from each of the Paretti cultures, but no bacteria resembling in their growth on gelatin the B. typhi abdominalis were found. Most of the bacteria developing in Paretti's solution from oyster-juice are anaërobic and are nearly all micrococci, so that they may be readily distinguished from the B. typhi abdominalis microscopically without making cultures on gelatin.

The following is a brief description of the kinds of bacteria found in oyster-juice which grow in Paretti's solution:

(*a*) In gelatin tube-cultures this presents almost no surface-growth, but shows as a white streak along the line of puncture. There is no liquefaction, and the growth is very slow at 72° F. On potato it forms an invisible growth.

Grown in peptone-solution it gives no indol-reaction. It turns litmus milk slightly acid. It is a micrococcus, sometimes arranged in strings like a streptococcus. It is harmless when injected into the peritoneal cavity of white rats.

(*b*) This bacterium grows dense, white, solid colonies on gelatin plates. The colonies are fairly round, but the outline somewhat dentated. After one week the colonies are nearly one-quarter of an inch in diameter. In gelatin tubes there is a thick, white, pasty surface-growth, with a good growth along the line of puncture. On potato it has a yellow growth. Under the microscope it shows large fat oval cocci.

(*c*) On gelatin plates the colonies of this bacterium are small, round and white, of slow growth. There is no liquefaction. In gelatin tube-cultures there is no surface-growth, and only a few small yellow globules along the line of puncture. There is no change in litmus milk—no indol-reaction is produced.

The microscope shows it to be a micrococcus.

(*d*) In gelatin plates the colonies after one week are minute specks. Under a one-half inch objective they appear as little, round, yellow drops.

On potato at 37° C. there is a white growth after twenty-four hours.

In gelatin tube-cultures there are little white specks along the line of puncture, with almost no superficial growth. After some days the gelatin becomes liquefied at the surface.

The microscope shows medium-sized micrococci.

Gelatin plates made with one drop of oyster-juice gave the following result:

Oyster 1. Large number of small, white colonies.
" 2. Innumerable, mostly liquefying bacteria.
" 3. Innumerable.
" 4. A few colonies.
" 5. Innumerable.

A few days later another experiment was made to determine more accurately the number of bacteria and the kinds found in oyster-juice. The gelatin plates were made with $\frac{1}{20}$ c.c. of juice in each plate. Nine oysters were examined.

---

[1] An analysis of this water showed it to contain 0.06 per cent. of salt.

Oysters.	Number of bacteria in $^1/_{20}$ c.c. of juice.	Number of varieties noticed.	Number of liquefying in each plate.	Kinds recognized.
1	18	5	2	
2	18	5	...	Many B. fluorescens liquefaciens.
3	12	5	...	B. gasoformans.
4	39	...	3	
5	43	7	5	B. fluorescens liquefaciens.
6	48	6	4	
7	12	4	2	
8	84	10	11	
9	34	...	9	

At the same time agar plates were made with $\frac{1}{20}$ c.c. juice of the same oysters, and the plates were incubated at 37° C.

Agar Plates of Oyster-juice.

	Number of colonies in $^1/_{20}$ c.c. of juice growing at 37° C.

" 2	3
" 3	Sterile
" 4	Many brown colonies
" 5	8
" 6	2
" 7	2
" 8	1
" 9	Many brown colonies

To determine whether the contents of the stomach contained any bacteria, the oyster was cut open with a sterilized knife and the surface of the stomach scraped with a loop of platinum; this was then drawn over a slant tube of agar. The loop of platinum was also plunged into the liver-substance, twisted around, drawn out, and rubbed over the surface of a slant tube of agar.

Agar Tubes made by drawing a Loop of the Contents of the Stomach over the Surface of the Agar. Tubes incubated at 37° C., Bacteria in one loop growing at 37° C.

" 5	1 col., B. megaterium.

A second experiment resulted as follows:

	Bacteria in loop of stomach-contents.	Bacteria in loop of liver-substance.
Oysters 1	1 col.	Sterile
" 2	Sterile	Sterile
" 3	Sterile	Sterile
" 4	Sterile	Sterile
" 5	A few colonies	A few colonies
" 6	Sterile	Sterile
" 7	Sterile	Sterile
" 8	Sterile	Sterile
" 9	A few colonies	Sterile

From these experiments we see that the number of bacteria in one cubic centimeter of oyster-juice which grow in gelatin range from 240 to 1680. The average number is about 684.

It may be of some interest to compare the number in the oyster-juice with the number in the water taken directly over where the oysters were growing. Samples of water taken directly over the oyster-beds and secured at the same time that the oysters were taken out of the water contained on an average 9520 bacteria in a cubic centimeter. Comparing this number with the number in the juice of the oyster we find that there are 8836 more bacteria in a cubic centimeter of the water surrounding the oyster than in the juice of the oyster. This indicates either that the juice of the oyster is destructive to certain bacteria or that the water undergoes a certain amount of filtration and purification in passing between the shells of the oyster.

The kinds of bacteria growing at 22° C. from the juice of the oyster are in most instances the same as those found in the water in which the oysters grow. Thus we find, among the more common varieties present, the B. fluorescens liquefaciens and the B. gasoformans. In one instance the B. megaterium was isolated from the stomach of an oyster. This bacterium, as is well known, is found on cabbage-leaves. There is a kind of seaweed, called by oystermen sea-cabbage, which is abundant around oyster-beds and on oysters. Whether this explains the presence of the B. megaterium in oysters I do not know.

Most of the bacteria found in the juice of the oyster do not grow at 37° C. By reference to the table of agar plates made from oyster-juice we see that there are rarely over 160 bacteria in one cubic centimeter of juice which grow at 37° C., and often there are not more than 20.

The examination of the stomach and liver of oysters shows in many cases that they are free from bacteria which grow at 37° C. The liver-substance was free in eight oysters out of nine, while the stomach was free from them in six out of nine.

I have studied chiefly the bacteria in oysters which grow at 37° C., as most growing at a lower temperature may be ruled out as a cause of disease. The bacteria from oysters growing in Paretti's solution I find, as a rule, quite different from those growing on agar plates. In the former case the bacteria are mostly anaërobic micrococci, while in the latter case they are aërobic bacilli.

Some of those growing in Paretti's solution, as already stated, resemble the B. typhi abdominalis by their invisible growth on potato, but are easily distinguished microscopically.

Two varieties isolated from agar plates liquefy gelatin rapidly, and are thus distinguished from the B. typhi abdominalis.

Three non-liquefying kinds were isolated from the agar plates, which in the early stages of growth on gelatin somewhat resembled the B. typhi abdominalis, but were easily distinguished from it by their growth on potato and in litmus milk.

Inasmuch as river-oysters, as a rule, are more exposed to contamination from sewage than oysters which are taken four or five miles away from any such source of contamination, from deep water, it seemed of interest to compare their relative infectiousness.

To do this bouillon-cultures were made by putting a half centimeter of the juice of an oyster into bouillon and allowing it to develop at a temperature of 37° C. for forty-eight hours. One cubic centimeter of this culture was then injected into the peritoneal cavity of a white rat.

Bouillon-cultures were thus made from seven river-oysters and from five oysters taken three miles out in Long Island Sound, south of the New Haven lighthouse. One cubic centimeter of each culture was then injected into the peritoneal cavity of white rats. After one month all of the five rats injected with bouillon-cultures from the sound-oysters were living and well; of the seven rats injected with bouillon-cultures of river-oysters five were living and well, but two had died.

One died three days after inoculation, the other six days after inoculation. From the blood and the liver of one of the rats a bacterium was isolated showing a white, round colony on agar plates, in litmus milk producing an intensely acid reaction, and producing a yellow slimy growth on potato.

From the blood, liver, and spleen of the other rat a bacterium was isolated, producing a brown growth on agar, with a green fluorescence. These experiments, as far as they go, seem to show a greater infectiousness of river-oysters.

It is an easy matter to determine the fact that the B. typhi abdominalis will live in oysters, but very difficult to tell whether it will propagate in them. A numerical estimation cannot be made of the number of bacteria in an oyster, even though we may know how many were introduced into it. It is clear, therefore, that conclusions in regard to number can be only very inexact.

My method consisted in cleaning a number of oysters and then injecting one cubic centimeter of a bouillon-culture of the B. typhi abdominalis with a Koch syringe between the edges of the shells. In this way a pile of oysters were infected. The oysters were kept in a cool room, the temperature ranging from 50° to 65° F. The vitality of the oysters was not apparently impaired by the operation, for, when opened subsequently, most of them appeared fresh.

Every few days one of the oysters was opened and agar plates were made from one-half a cubic centimeter of juice. The surface of the oyster over the stomach was then scorched with a red-hot iron, and the stomach was opened with a sterilized knife. A loop of the stomach contents was then drawn over a slant tube of agar. The plates and tubes were kept at 37° C.

In this way it was thought that if the B. typhi abdominalis multiplied, the agar plates and slant tubes for each succeeding oyster would show a greater number of the B. typhi abdominalis than the oysters opened before it; while if the B. abdominalis died, the juice of succeeding oysters would show a quick decrease in number.

Occasionally an oyster was opened which had lain in the same room with the other oysters, but had not been infected with the B. typhi abdominalis. Plates were made from the juice and slant tubes from the stomach, as a check on the method.

As a preliminary experiment, some of the juice of a large oyster was drawn off with a sterile pipet, put into a sterilized test-tube, and infected with a loop of a culture of the B. typhi abdominalis.

Every few days agar plates were made with two loops of this juice. The tube of juice was kept at a temperature of between 60° F. and 70° F.

The results were as follows:

Oyster opened and juice drawn off on December 21st.

	Number of colonies in two loops of juice after infection.	Number of colonies in two loops of juice before infection.
Plate of Dec. 21st . .	Innumerable colonies of B. typh. abd.	Sterile.
" Dec. 23d . .	" " " "	
" Dec 27th . .	" " " "	
" Dec. 31st . .	About 100 cols. of B. typh. abd.	
" Jan. 10th . .	One or two cols. of B. typh. abd.; plate overgrown with other bacteria.	

The following is the record of results with living oysters:

Oysters Injected with Bouillon-culture of B. typh. abd. on January 16th.

Oyster A. Opened January 17th.
½ c.c. juice contains innumerable cols. of B. typh. abd.
Stomach, a few cols. of B. typh abd.

Oyster B. Opened January 19th.
½ c.c. juice contains innumerable cols. of B. typh. abd.
Stomach, 50 or 60 cols. of B. typh. abd.

Oyster C. Opened January 22d.
½ c.c. juice contains 200 cols. of B. typh. abd.
Stomach, 2 or 3 cols. of B. typh. abd.

Oyster D. Opened January 24th.
½ c.c. juice contains innumerable cols. of B. typh. abd.
Stomach, about 14 cols. of B. typh. abd.

Oyster E. Opened January 28th.
½ c.c. juice contains innumerable cols. of B. typh. abd.
Stomach, sterile.

Oyster F. Opened January 28th. Check from pile not inoculated with B. typh. abd.
½ c.c. juice, sterile.
Stomach, sterile.

Oyster G. Opened February 2d.
½ c c. juice contains about 60 colonies of B. typh. abd.
Stomach, sterile.

Oyster H. Opened February 13th.
½ c.c. juice contains about 40 cols. of B. typh. abd.
Stomach, 3 cols. of B typh. abd.

In stating the number of colonies of the B. typhi abdominalis an exact number cannot be given, as there may have been in some instances other kinds of bacteria present which were mistaken for the B. typhi abdominalis. In general, however, the number is approximately correct, as cultures were made from some of the colonies of every plate, in litmus milk and on potato, and the mere plate appearance was not alone relied upon to determine whether I was dealing with the B. typhi abdominalis or some interloper.

These experiments do not throw very much light on the question of the multiplication of the B. typhi abdominalis in oysters. They do, however, seem to show that if multiplication does occur it takes place within the first two weeks, and that after that there is a progressive decrease in the number of the B. typhi abdominalis found in oysters, but that it may be found even after thirty days from the date of infection. They further show that the B. typhi abdominalis not only lives in the juice, but penetrates into the stomach and lives there for some time. In fact the B. typhi abdominalis lives longer in the juice and stomach of the oyster than it does in the water in which the oyster grows.

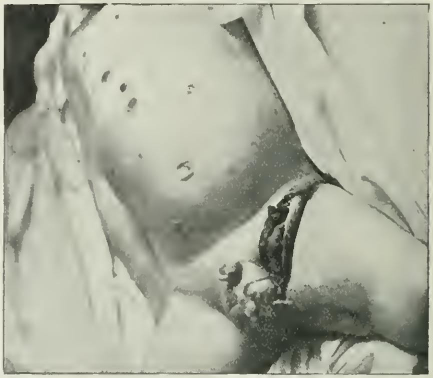
CLINICAL MEMORANDA.

VARICELLA COMPLICATED BY GANGRENE OF THE SCROTUM.[1]

BY CHARLES D. SPIVAK, M.D.,
OF PHILADELPHIA.

JONATHAN HUTCHINSON was the first to draw the attention of the medical profession to a complication of varicella characterized by the development of gangrene of the skin and deeper tissues at the the site of the eruption. Since his memorable article on "Gangrenous Eruption in Connection with Vaccination and Chickenpox,'"[2] similar cases have been reported from England by Abercrombie,[3] Martin,[4] Howard,[5] Jamieson,[6] Andrew,[7] Bowlby,[8] Payne,[9] Crocker,[10] and Stanifooth.[11] The United States and Germany are represented in the literature on the subject by two authors each: the first by Woodward[12] and A. F. Büchler,[13] and the second by Demme[14] and Cassel.[1] Whether the children of other nationalities are exempt from this complication, or the cases have not been reported, I do not undertake to decide. So far as my researches go I have been unable to find a single case in French, Italian, Russian, or Spanish medical literature. The rarity of the complication in general, and the exceptional features of the case that came under my treatment in particular, seem to justify me in reporting it.

The patient was a boy of Russian parentage, aged two years, whose father and mother are healthy, with no scrofula or tuberculosis in the family, and with five other children all well and healthy. He had had no serious illness previous to the attack of chickenpox. As I saw the case for the first time only on the eighth day of the disease I have to rely upon the data furnished by the parents, who proved to be tolerably good observers and quite reliable. On November 25, 1894, the chickenpox was noticed for the first time; on the 26th the child became restless and had fever; on the 27th the fever increased, the child was delirious, and the scrotum became red and swollen. This state continued until the 30th, when the swelling extended to the left inguinal region; a black spot the size of a pin-head had appeared on the left side of the scrotum, and soon several others formed a circle around the original one and coalesced. On the following day another black spot appeared a little further to the left on the scrotum, and "before one had time to look at it," as the parents expressed themselves, the process of deep ulceration and "eating up" commenced. On December 3d I saw the child for the first time. It was well preserved and plump, as seen by the photograph and by its appearance now, and somewhat irritable. The penis, the scrotum, and the left inguinal region were very much swollen and tender. The left side of the scrotum was covered by blackish, muddy-looking crusts and detritus covering about two-thirds of it and passing over the raphe to the right side. The smell was very offensive. The crusts and detritus were carefully removed and the tunica albuginea of the left testicle was exposed to view, thus showing that the gangrenous process destroyed not alone the integument but also the dartos, the external, cremasteric, and internal fascias, and the tunica vaginalis. There was a distinct areola around the ulcer. The presence of pus in the inguinal region was easily demonstrated by fluctuation and also by the oozing from a very small spontaneous opening found about half an inch from the scrotum. The temperature was 101.6°, the pulse 110. Pressure over the bubo gave pain, but the handling of the ulcer was almost painless. I washed the parts with mercuric chlorid and applied an iodoform-gauze dressing and a bandage. On the following day, when the bandage was removed, the ulcer was found to present a somewhat better appearance, but was still angry-looking and covered with pus from the oozing aperture. The child was anesthetized by Dr. Rachel Skidelsky, and introducing the grooved director through the opening I laid open the inguinal region throughout its length, as shown in the photograph. I cleansed the wound thoroughly and packed it with iodoform-gauze. (The photograph was taken at this juncture, and shows the incision with the packing in it; the left testicle exposed and many spots of dried-up vesicles all over the body.) The ulcer was



---

dressed with mercuric-chlorid gauze saturated with hydrogen dioxid, and a T-bandage applied. Of course, the ulcer required a good deal of trimming for the removal of dead tissue. I ordered two grains of quinin to be given in the evening and two grains in the morning. It was then that I noticed that three children in the same family had varicella in different stages of development. There were no complications in the other cases.

On the following day the temperature fell to 99.2°; the child slept almost the whole night, the first time since it had been sick; the ulcer and wound were clean and the gangrenous process checked. The local treatment was continued the same during the entire period of the regeneration of the scrotum, which took about thirty-five days. The repair is complete and admirable, leaving only a star-shaped cicatrix. No internal treatment was needed after the third day.

Through the kindness of Dr. J. S. Billings, Deputy Surgeon-General U. S. Army, I was enabled to trace the literature on the subject antedating the report of Hutchinson. Besides the mention by Hutchinson of two cases in Guy's Hospital Museum, which were named varicella escharotica, and the case of Stokes described in 1807 in his *Dublin and Physical Essays on Eruptive Diseases of Children*, which he named pemphigus gangrænosa, and which, according to Hutchinson, are to be regarded as cases of varicella gangrænosa, the following cases were reported and minutely described by their respective authors as varicella complicated by gangrene: Dr. Humphrey Storer,[1] Steinthal,[2] Loewenhardt,[3] Dr. Frederick J. Brown,[4] of Rochester, and Dela Harpe.[5]

529 PINE STREET.

TEN CONSECUTIVE CASES OF DIPHTHERIA TREATED WITH THE ANTITOXIN.

By CHARLES S. SMITH, M.D.,
OF ELROY, WIS.

I WAS called, February 4, 1895, to see Mrs. V., aged twenty-four years, who was suffering with sore-throat, headache, fever, and general malaise. On examination I found the surface of both tonsils covered with diphtheric deposit. No antitoxin was used in this case, as there was none to be obtained. The usual remedies, swabbing, spraying, etc., used. After about ten days the patient was convalescing and made an uneventful recovery.

CASE I.—Six days after Mrs. V. was taken sick her eldest son Philip, aged four years, developed diphtheria, with a thick deposit over both tonsils. The pulse was 120, the temperature 99°. There was used in this case Behring's antitoxin, No. 2, ♏x. The next day the pulse was 112, the temperature normal, and the deposit on the tonsils began to peel off. Antitoxin, ♏xx, was used. On the third day the patient was convalescing and practically well.

CASE II.—Frank V., of the same family as the preceding case, aged two years, when seen had been ill thirty-six hours. There was a diphtheric deposit on both tonsils. The pulse was 152, the temperature 99°. Antitoxin No. 2, ♏x, was injected, and twenty-four hours later the pulse was 132, the temperature normal; the countenance and general aspect of the child improved. There still remained patches in the throat, and ♏xv more of antitoxin were injected. On the third day the child was practically well.

CASE III.—Mary S., aged sixteen years, had been sick one week with sore-throat when I was called. On examination I found the whole surface of both tonsils leading into the nasal cavities covered with diphtheric deposit, from which emanated an odor so offensive that one could hardly remain in the room; ♏40 of Behring's antitoxin, No. 2, were injected. I also used an antiseptic spray, together with quinin and morphin, to give rest. On February 13th, twenty-four hours afterward, ♏30 of antitoxin No. 2 were injected. (I should have used more, but this was all I had at the time.) On February 17th the patient was much improved, and there was exfoliation of large amounts of membrane. (A large mass of membrane was placed in a bottle and sent to Dr. C. E. Booth, Low Moor, Va., for microscopic examination. He reported that the Loeffler bacilli were present.)

Having obtained a new supply of antitoxin No. 1 I gave ♏40 on February 19th; the patient convalescing, ♏30 more were injected. On February 20th the throat was entirely clean, the pulse 100, the temperature 98.5°. The patient was practically well, with the exception of paralysis of the throat, difficult articulation, etc. After seven days' treatment the patient had so far recovered as to be able to care for others of the family who were ill.

CASE IV.—Otto N., aged nine years, was of the same family as the preceding case. When seen he had been ill twenty-four hours, with headache, sore-throat, etc. The pulse was 120, the temperature 101°; ♏60 of antitoxin No. 1 were injected. On the third day the pulse was 116, the temperature 98.5°. Antitoxin, ♏40, was again used. On the fourth day of the sickness the pulse was 80, the temperature 98.5°, the throat was clean, and the patient was about the house.

CASE V.—On February 18th, Bertha M., aged three years, had been sick four days before I was called. On examination I found the tonsils and uvula covered with diphtheric deposit. The mother and sister in the same family were also sick with diphtheria. I used ♏60 antitoxin on February 19th, ♏40 on February 20th, and ♏30 February 23d. The throat now became clean and the child was rapidly convalescing. This was practically all the treatment used, as the child was unruly and hard to manage; therefore, any local or constitutional treatment was impossible. The membrane was also examined in this case, and diphtheria-bacilli found.

CASE VI.—On February 19th I was called to see a German family, five of whom had been sick for twenty-four hours with diphtheria. Antitoxin was used in all these cases, and within five days all were as well as ever.

Dr. Robert Bruce Mowrey, the oldest physician in Allegheny County, died on March 14th, at Pittsburg, at the age of eighty-one years. He was graduated from Jefferson Medical College in 1836. He was a member of the American Medical Association and of the Medical Society of the State of Pennsylvania, and an honorary member of the Medical Society of the State of California. He was one of the founders of the Allegheny General Hospital.

CLINICAL REPORT OF SEVEN CASES OF VARICOCELE TREATED BY INCISION, DELIGATION OF VEINS, AND SHORTENING OF THE SCROTUM.[1]

BY W. E. PARKER, M.D.,
OF NEW ORLEANS.

I HEREWITH present the histories of seven cases of varicocele that I have treated by a method that is simple, that does not require any complicated instruments, and that has been very satisfactory in its results. The operation is performed as follows:

An incision, varying in length according to the size of the varicocele, is made directly over the mass of veins. The varicose veins are then ligated in two places, removed, and the stumps brought together. The ends of the incision are then brought together, and the wound changed from a longitudinal to a transverse one. The incision should be sufficiently long to bring the affected side of the scrotum well above the other. There is a slight redundancy of tissue at the ends of the wound when closed, but this in time does not show so markedly as at first, although still present in all of my cases. The operation is easily performed, and requires but few instruments; one can see what he is doing, and there is no troublesome hemorrhage. Fearing that the shortening of the scrotum might not last, I had intended to remove with a pair of curved scissors an elliptical piece of the scrotum and then sew the wound transversely in my future cases, but have not recently had a case that required operation, and my results have been so satisfactory with the method I have used that I think I shall continue to use it. No drainage-tube was used in any of these cases, and all recovered, with union by first intention and without any complication. Briefly, the histories of my cases are as follows:

CASE I.—G. B., a laborer, aged thirty-two years, white, came to the out-door clinic of the Charity Hospital May 14, 1894. He has had dull pain in the left testicle and groin for the past year, which has increased in the past three months. He masturbated in boyhood, but not since. He is constipated. He had epididymitis three years ago. On examination a large varicocele was found, the left testicle hanging much lower than the right. He was admitted to the ward, and that night given ℥ss magnesium sulphat, and the parts were shaved and prepared for operation, which was performed the next day. The wound healed kindly, and the patient was discharged, cured, June 3d. I saw this patient five months after the operation. He is still well, and the left testicle still hangs well above the right.

CASE II.—Ed. W., a negro, aged thirty-four years, a laborer, came under observation June 19th, having a large varicocele of the left side. He had orchitis five years ago, and suffers from constipation. He was operated upon on June 20th. The wound healed by first intention, and the patient was discharged, cured, July 5th. This case especially interested me on account of his race. In a service of three years in the negro male surgical service, and one year in the male genito-urinary clinic of the Charity Hospital, where about two-thousand cases per annum are treated, I have seen but two cases of varicocele in the negro. I have not seen this man since he was discharged from the hospital.

CASE III.—Mr. T., aged twenty-nine years, a clerk, of German descent, is an epileptic, and believes that his varicocele causes the convulsions. The varicocele is rather large. He was operated upon on June 2d. The wound healed kindly and under one dressing. I saw him in the early part of October. The varicocele was well, and the left side of the scrotum was still higher than the right. He thinks the convulsions are less frequent and less severe.

CASE IV.—Albert H., aged twenty-six years, a laborer, has had epididymitis and is constipated. He noticed the varicocele five or six years ago, but it did not trouble him until the past year. He was operated upon on June 27th. The wound healed nicely, and he was discharged July 10th. He returned the latter part of September with chancroids, the varicocele well, and the left side of the scrotum still higher than the right.

CASE V.—I saw this man, Mr. J., in consultation with Dr. R. DeMontluzin. The operation was performed on July 5th. The man was discharged July 15th. He had a large varicocele, which he thought interfered with his sexual powers. Dr. DeM. tells me that he is now perfectly well, and that the left side of the scrotum is still higher than the right.

CASES VI and VII were both clerks, one nineteen and the other twenty-one years old. Both were of nervous temperament, but there was nothing else in their history to show the cause of the varicocele. Both were operated upon in July, and the result up to date is satisfactory.

Such is the history of my cases of varicocele treated in this way. I like the method of changing the wound from a longitudinal to a transverse one, because it shortens the scrotal hemorrhage or bruising. Should the scrotum become lower on the left side than on the right I would in the future remove the elliptical piece, as I have suggested.

I think that the milder cases of varicocele should be treated with a suspensory bandage, with proper regulation of diet, exercise, and the bowels. I think a varicocele should be operated upon:

1. If it is of large size. 2. If it is very painful. 3. If there be marked nervous symptoms present. 4. If the testicle is atrophying. 5. If the varicocele is increasing rapidly. 6. If it is an obstacle to entering public service. 7. If on account of the patient's occupation a suspensory bandage is troublesome and he desires an operation.

I do not claim that this method of shortening the scrotum, by converting a longitudinal incision into a transverse one, is new, but I have never heard of anyone else using it.

MEDICAL PROGRESS.

Abscess of the Left Occipital Lobe Causing Object-blindness and Word blindness.—CAMPBELL (*Liverpool Medico-Chirurgical Journal*, 1895, No. 28, p. 52) has reported the case of a man, forty-three years old, whose occupation rendered him liable to exposure in all kinds of weather and entailed irregularity of meals. There had been deafness in the left ear for thirty years, and for ten years a discharge from this ear. Examination disclosed perforation of the tympanic membrane with granulations. For three or four months there had occurred attacks of giddiness, and on one occasion the man became suddenly confused, lost his feet, and was completely aphasic. Consciousness was not lost, and the man was soon able to go on his way. On the following morning the power of speech had returned and all locomotor disturbances had disappeared. When seen a month later the man was in a state of mental depression and complained of a sense of oppression at the vertex. He presented object-blindness (inability to recognize objects), word-blindness (inability to interpret printed symbols), paralexia (misuse of words in reading), and paragraphia (the misspelling of words and the incorrect arrangement of their letters). Occasionally words were transposed in ordinary conversation. There was no word-deafness.

---

[1] Read at the meeting of the Southern Surgical and Gynecological Association, Charleston, November 15, 1894.

While under observation the man had several seizures similar to that already described, always becoming absolutely aphasic and confused for from twenty to thirty minutes after the attack, and occasionally losing the power of the right arm and leg, which during the seizure were convulsed. He began to complain of left-sided occipital headache, which became constant and intense, lost his memory, acquired delusions of persecution and visual hallucinations, refused food, and became violent toward his wife. Ophthalmoscopic examination disclosed marked double optic neuritis with hemorrhages. The right half of the visual field was limited. There existed homonymous hemianopsia. There was no absolute color-blindness, although there was uncertainty in distinguishing various shades of the same color. The right pupil was slightly the larger; both reacted to light and in accommodation. The knee-jerks became exaggerated. The man grew progressively worse, and toward the end of his illness there was some general diminution of sensation. Finally he became stuporose, and ten days before death, which resulted from respiratory failure, rotatory nystagmus in all directions, ataxia, and special weakness of the trunk-muscles were observed.

Upon post-mortem examination the inner surface of the calvarium yielded a prickly sensation to the tip of the finger, from the presence of numerous extremely delicate osseous spicules. The left hemisphere was considerably larger than the right, and was obviously bulged in the occipital segment. This bulging began internally opposite the anterior margin of the precuneus; it flattened all the sulci, particularly the parieto-occipital, from within outward and extended backward to the tip of the occipital lobe, which was rounded instead of being pointed. A corresponding part of the outer surface of the hemisphere was also bulged. The surface of the hemispheres was of pale color, but over the swollen left occipital segment it was distinctly reddened and betokened subjacent inflammation.

On horizontal section, the swelling was found to be due to a centrally situated abscess of the size of a turkey's egg. The abscess was round in shape, and, from the thickness and roughness of its walls, presented an encapsulated appearance. The surface-tissues covering the abscess, though unbroken, were much thinned and undermined. The nearest point to the surface which the abscess reached was at the parieto-occipital fissure. The white matter surrounding the abscess was softened and inflamed, and this inflammatory condition encroached on the center of the hippocampal and uncinate gyri, the subcallosal fasciculus, the posterior pillar of the fornix, the optic thalamus, and the tegmentum cruris of the left side. The posterior horn of the lateral ventricle was not broken through. The ventricular fluid was diminished in amount, but of normal quality. The upper surface of the cerebellum was flattened, softened, and congested. The olfactory bulbs were slightly flattened. The lungs presented some patches of lobular pneumonia, but the remaining organs were healthy.

On microscopic examination of the pons small hemorrhages were found in the region of the red nuclei. There was some descending degeneration in the left lemniscus and posterior longitudinal bundle, probably in consequence of the softening of the left optic thalamus. Some degenerative fibers were visible in the left and right superior and middle cerebellar peduncles and in the left pyramidal bundles; the latter were followed down the spinal cord. In the medulla some degeneration was found in the restiform bodies. This could be traced into the cuneate nuclei, thence into the funiculi cuneati, and thence into the posterior external columns of the spinal cord, down which it could be followed as far as the point of origin of the ninth dorsal pair of nerve-roots. Some fibers in the anterior and posterior nerve-roots were degenerated, but definite degenerative changes in the cornual ganglion-cells could not be found.

On the Measurement of Simple Reaction-time for Sight, Hearing, and Touch.—At the last meeting of the British Association for the Advancement of Science, Professor W. Rutherford, M.D., F.R.S., presented a communication detailing that in observations made on eight intelligent, healthy men, varying in age from nineteen to sixty-two years, the reaction-time for sight varied from 0.1662 second to 0.2202 second, and was mostly between 0.20 second and 0.22 second. The reaction-time for hearing varied from 0.1448 second to 0.1930 second, and was mostly between 0.15 second and 0.16 second. The reaction-time for touch varied from 0.1416 second to 0.1906 second in the different cases. The shortest touch reaction-time is that following stimulation of the cheek; it varied from 0.141 second to 0.157 second. When the skin of a finger was stimulated the reaction-time varied from 0.142 second to 0.190 second, but was mostly from 0.15 second to 0.18 second in the different cases; there was no evident relation between the age and the length of reaction-time in the cases under observation. In a limb the reaction-time is generally longer the greater the length of sensory nerve traversed by the impulse; but there may be considerable variations in the reaction-times for different districts in the field of touch not explicable by difference in the length of sensory nerve traversed, but probably due to difference in the closeness of relation between centers for tactile sense in the brain and the motor center for the hand. It may, therefore, happen that a response is given sooner by the hand when its skin is stimulated than when the mucous membrane of the tongue is stimulated, although in the latter case the impulse has a much shorter tract of sensory nerve to traverse. When the right hand gives the response the shortest reaction-times for hearing and touch are obtained by stimulating the right ear and the right cheek. In the experiments on sight, both eyes were used at the same time. The influence of fatigue on reaction-time and the remarkable restorative effect of tea were demonstrated by photographs.

Frog-skin Grafting.—SMITH (*Boston Medical and Surgical Journal*, vol. cxxxii, No. 4, p. 79) has reported the case of boy, five years old, who suffered a deep and extensive burn, involving an area of the trunk, face, and neck. The part involved was bounded by a line extending from the thyroid cartilage down the median line of the body to within an inch of the umbilicus; thence around the trunk to the median line of the back; from here up to the external occipital protuberance; thence to the malar bone on the left, including a portion of the ear; diagonally across the face to the right angle of the mouth, and finally reaching the thyroid cartilage.

When seen, four weeks after the accident, the entire surface was covered with healthy granulations that bled freely upon the slightest touch. The fold of the axilla had become firmly adherent to the chest, binding the arm firmly down. To expedite recovery, and in view of the unfavorable condition of the subject, grafting with the aid of frog-skin was decided upon. Small pieces, each a quarter of an inch square, were placed in rows, each separated from the other by a space of half an inch; and this was repeated until, after the lapse of seven weeks, the whole surface was covered. The treatment was repeated daily, from twenty to eighty frog-grafts and a smaller number of human grafts being used on each occasion. The surface was first cleansed by irrigation with a warm solution of boric acid 1 to 40, and subsequently washed with a stream of sterilized water. Each graft was then firmly pressed into the granulation-surface, and subsequently a dressing of boric acid and vaselin, a dram to the ounce, was spread upon strips of compressed cloth and applied so as to fit the parts. Over this was placed sterilized gauze and finally a rubber bandage. In all nearly a thousand frog-grafts and four-hundred human grafts were used.

Pylorectomy for Carcinoma.—JESSOP (*British Medical Journal*, No. 1778, p. 189) has reported the case of a woman, forty-nine years old, in which pylorectomy was performed for the relief of obstruction of the pylorus by malignant disease. In the course of a few months the woman resumed her ordinary duties, and three years later she appeared in good health. The tumor removed was an inch-and-a-half long and six inches in circumference. The pyloric opening barely admitted the tip of the little finger; the stomach-wall was much thickened; the duodenal wall less so. At the lower part of the pyloric opening was a saucer-shaped ulcer of the size of a shilling, with a thickened base. Microscopically the tumor consisted principally of densely packed fibrous tissue, with intervening small round cells, and here and there in the interstices of the fibrous tissue were the remains of degenerated glands, which were numerous in the deeper layers of the section outside the fibrous tissue.

Suppression of Urine in Diphtheria.—GOODALL (*Lancet*, No. 3727, p. 269) calls attention to the occurrence of urinary suppression in the course of diphtheria in the absence of distinctive lesion of the kidneys, and cites six illustrative cases.

In one there was total suppression for nearly seventy hours before death; in a second for fifty-seven hours; in a third almost total suppression for forty-two hours; in the fourth, partial suppression for some days and total suppression for twenty-four hours; in the fifth, partial suppression for four days, and in the sixth, the only one in which recovery ensued, the amount of urine was notably diminished for a period of fourteen days. All of the cases were severe and presented albuminuria. Besides the anuria there was often vomiting, and symptoms of cardiac failure were nearly always present, death often taking place from this cause. There was usually also much local exudation upon the fauces.

THERAPEUTIC NOTES.

The Treatment of Erysipelas with Strong Alcohol.—LANGSDORFF (*Centralblatt für Chirurgie*, 1895, No. 8, p. 189) reports the employment of topical applications of strong alcohol in the treatment of thirty-two cases of erysipelas. Soft, thick linen compresses are saturated with the alcohol, and are renewed every fifteen or twenty minutes, being covered with dry cloth and gutta-percha tissue. If the face is affected, cotton compresses are used instead of linen as adapting itself better to the irregularities of the surface. The compress must be saturated with alcohol, and should be frequently changed. In all cases thus treated the symptoms speedily receded. Some little discomfort was experienced from the applications when the face was involved and in the case of sensitive persons who were unpleasantly affected by the odor. The redness and tension often disappear in the course of eight or ten hours, after which the intervals of application may be lengthened. Recovery, as a rule, resulted in the course of two or three days. If the morbid process manifested a disposition to extend, the applications were made to include the new areas involved. For the dryness of the skin following the applications lanolin was found serviceable. Official absolute alcohol diluted with 1 per cent. of water was employed.

Gallanol.—JOSEPH (*Berliner klinische Wochenschrift*, 1895, No. 8, p. 164) reports results obtained from the employment of gallanol, the anilid of gallic acid, in the treatment of various diseases of the skin. He found the remedy not to be compared with chrysarobin in activity and efficiency in the treatment of psoriasis, but applicable in the milder forms and when rapidity of result was not essential. Gallanol has the advantage of not soiling the hair, the skin, and the linen. The remedy was employed in a 10 per cent. traumaticin-solution, and for psoriasis of the head and face in the form of a 10 per cent. ointment. The remedy proved less successful in the treatment of eczema. In this condition it was employed in the form of powder in various concentrations. It was likewise employed as an ointment in varying strengths, but no influence was exerted either upon the eczema or upon the itching. The results in herpes tonsurans and eczema marginatum with a 10 per cent. solution were similar to those obtained in the treatment of psoriasis.

GYNECOLOGY AND PSYCHOLOGY.

WHEN ARETAEUS described the womb as an animal within an animal, wandering about, attracted by fragrant things and fleeing from fetid, he foresaw, as through a speculum dimly, the era of modern gynecology. When PLATO said that the womb is desirous of generation and that, if unfruitful, it turns indignant and wanders about the body, stopping the passage of the humors, he clearly indicated the necessity, in some cases, for a modern hysterectomy. When PAUL, of Aegina, declared that hysteria is caused by putrid secretions in the uterus, he discerned, as with prophetic vision, the fountain-syringe and a 1–4000 solution of mercuric chlorid.

Thus, in the dawn of science, the errant womb, issuing from prehistoric darkness, with a train of sacrificial priests, appears already surrounded and obscured with a mysterious *cult*. Not even phallic worship—potent enough in all ages—will hold the world-stage with her. On through the ages, behind her impenetrable veils, with which conventionality had replaced her primitive fig-leaves, she comes claiming the allegiance and the worship of men. Thus she advances, with her rites almost unchanged, to the modern era.

We are now in the period, however, in which the sacrifices are too suggestive of human blood; in which the penance is too exacting of human hopes and reason. Let us explain ourselves.

The theory of the psychologic school of gynecologists is that the womb and its appendages are the etiologic factors in some forms of insanity. Therefore, they advise that the cause be removed; that the ovaries especially, and, if opportunities are favorable, the womb itself, be cut out. In this their *confrères* of the gynecologic school of psychologists in the main agree with them, only urging that due caution be had for Boards of Directors and Trustees.

According to this theory, the "mind," having been freed from the assaults of the erratic womb, ought to swing at once into static equilibrium. Possibly it would do so if it were simply the inert mass that this theory seems to presuppose it to be. But it is not an inert mass, simply acted on *per vaginam*. No speculum has yet explored its hidden mysteries; no celiotomist has yet penetrated through *its* walls to the complex source of its diseases. It is not a mass receiving its impulses from a body of unstriped muscular tissue. It is an assimilating "psyche," and, unfortunately, when insane it grows by what it feeds on. It can, moreover, just as readily feed on a gynecologic operation as on more wholesome and inviting food. All of which has been illustrated to us recently by a most instructive case.

An unmarried woman, of highly nervous organization and with a constitutional tendency to imperative conceptions (mental, not uterine), was relieved of her womb and ovaries by an enterprising surgeon. There is no question that the womb was diseased, having undergone some fibroid enlargement. It had not, however, interfered with her health, which was impaired only by beginning delusional ideas, which were commencing to control her. She made, rather unfortunately it seems for her, an uninterrupted recovery; and we have no doubt that her case has gone to swell the records of "successful" operations reported by this particular surgeon.

During this first stage of her disease it seems that an expert study of her mental condition was not made; this was done some months later, when she had graduated from the gynecologic ward into an insane-asylum. The complexus of her delusions, then, was about as follows:

Starting with the operation she reasoned (if one may call it reason) that she had furnished, not a *successful*, but a *fatal* example; and this, especially, because the operation in her case had been so well done. This very fact—such was her insane logic—would induce this particular surgeon, and other surgeons who should hear of her case, to perform other operations, and would encourage other patients to submit to them. Because of the tendency, which she knew existed in some surgeons, to remove the uterine appendages for nervous conditions on small provocation, she believed that she was morally responsible in having encouraged them, and that in cases of fatal results the sin (?) would be on her head. In addition to this obliquity of thought, she suffered from her reflections on the results in her own case. She apparently felt that she had dishonored herself in submitting to an act which, to her supersensitive mind, was shameful in that it had resulted in *unsexing* her. Because of this train of ideas she had become profoundly melancholy, and had suicidal impulses.

Comments on this case may be brief. In the first place, we do not share the patient's insane idea that she or her surgeon is culpable. We freely give the surgeon credit for having acted from an honorable and, as it doubtless seemed to him, a scientific motive. We judge the case purely from the psychologic standpoint. We point out the fact that radical operations in the genital zone may be performed with a two-edged scalpel, which may cut in an entirely opposite direction from what was intended. Such an operation must be studied in its effects upon the patient's mind; not in the intentions of the surgeon, nor in the purely surgical result. We perceive clearly that in the case here cited the operation undertaken has supplied the whole pabulum for a grave psychosis—a fact to the possibility of which gynecologists are too often blind. If it were an isolated case, we might not care to draw too sweeping a deduction from it, but unfortunately we have known others like it.

In the second place, the operation, as has been justly said, is one of that small class that are condemned by their very successes. This is strikingly shown in the case of this poor woman, whose most disturbing thought is that she has furnished an example.

Finally, the case illustrates how easy it is in these patients to disturb the moral *ego* whose seat is in a wandering brain instead of in a rampant uterus.

NO STATE APPROPRIATIONS WITHOUT STATE SUPERVISION.

The work of apportioning the State money among the Pennsylvania charitable institutions that apply for assistance has grown to such an extent that it is beyond the power of the Appropriation Committees to give it the proper attention and so to divide the money that it will go to the most deserving. Representative Fow has introduced a bill that aims to regulate the disposition of State moneys to charitable and other institutions not directly under the control of the State, by providing that the Senate and House, by a two-thirds vote, shall appropriate at every session such moneys as may be left in the State Treasury after the Executive, Legislative, Judicial and other State departments, penal institutions, State hospitals and all other State institutions absolutely under State control have been provided for, to the Governor, Lieutenant-Governor, Attorney-General, State Treasurer, Auditor-General, and Secretary of Public Charities, as Trustees, to make such division among those asking for State aid as are legally entitled to it, in such proportions and such amounts as may seem to them fit and proper.

In New York City a bill making an appropriation for a lying-in asylum is the latest of a series of acts passed during the last thirty years compelling the city to appropriate moneys to charitable institutions wholly or partly under private control. In this bill an endeavor seems to have been made to conform to the provision of the new Constitution that payments by cities to charitable institutions may be authorized, but shall not be required by the Legislature; but the attempt has not been successful, and the act is clearly in violation of the Constitution. The introductory clause of this act provides that "the Board of Estimate and Apportionment *shall* annually include in its final estimate the following sums, which *shall* annually be raised and appropriated." This clause has always been construed to be mandatory, and it is under this act that the Board of Estimate and Apportionment has appropriated $1,478,723.00 for the support of charitable institutions during the present year. The lying-in asylum act *permits* the city authorities to provide an appropriation for the current year, but it will *compel* such appropriation in succeeding years, and is mandatory in the fullest sense of the term.

Thus, in the great States of Pennsylvania and New York almost the last vestige of economy, control, and justice in reference to appropriations to private institutions is thrown away, and all corporate bodies of men, with so-called charitable institutions in front of (or behind) them, are to be permitted to divide between themselves all the money not needed for legal and necessary State purposes. It is a question of rushing in and grabbing what is left, and the State is to have absolutely no oversight or control as regards the honesty or methods of spending the money. In these days of sharp competition in the hospital business, in these days when hospitals pay money to advertise for patients, could anything be more unbusiness-like, barbarous, disgusting? In New York many abuses have been brought to light as the result of such unaccounting and unaccountable use of money. One institution received in 1893 from the city $93,291, and expended but $76,803, leaving a net profit of $16,488.

This yearly scramble, with payment of lobbies and attorneys, by hospitals and asylums, is a remarkable product of nineteenth-century statesmanship. The unreasoning public thinks either that whatever is called a hospital is holy and blessed, or, with true Socialistic cunning, is very willing to get medical services for nothing. Then, again, one hungry and clamoring, but worthy, institution cannot say a word about its unworthy neighbor, equally famished and greedy, and so, regardless of merit or right use of the money, all fight for "the remains of the feast," and that one that has the best "political pull" gets the most. But all get something, because the poor bedevilled legislators or members of committee must all shut their mouths.

Now, it is an open secret among medical men that the motives of the men governing and using dispensaries and hospitals are by no means always pure and unselfish. Many hospitals are founded and carried on neither solely for the love of science, for the benefit of the profession, or for the love of humanity. It is also fast becoming recognized that treating people's diseases indiscriminately without payment therefor is often as great an injury to society as to the medical profession. All that goes under the mask of charity is by no means charitable, and nowadays discrimination in benevolence is quite as obligatory as benevolence itself. But, with the hundred of institutions of true charity that modern civilization demands of the State, but which as yet are unsupplied; with the absolute certainty of a reduced death-rate from the application of scientific sanitation; with preventive medicine guaranteeing fifty or one-hundred per cent. interest on every dollar of outlay—with these and the like knowledge of the *causes* of disease upon our consciences, it is to play the part of the most asinarian of asses to throw away hundreds of thousands, nay millions, of dollars upon the individual and ever-recurring *results* of disease—and that without a thought or a glance of subsequent control or of supervision. Why should not these hospitals supported by the State care *pro rata* for the pauper sick? Why should the taxpayers pay first the private hospital for services it will not render, and then these same taxpayers be compelled to keep their own city hospital? It is an outrage both to American financial ability and to the rare article called "common" sense. Let the fundamental principle hereafter govern all distributions of State moneys to private charitable, or supposed charitable, institutions: *No State appropriations without strict accountability and State supervision!*

EDITORIAL COMMENTS.

The Protection of Non-motormen.—The ministerial unions, we learn from the daily press, are stirring themselves up in behalf of the motormen. The motormen are too much exposed to the weather, and should, in the opinion of some ministers, be enclosed in glass houses—before summer, we hope. But the old proverb about glass houses, like most old proverbs, holds good, no matter how we twist its application. In their glass cages the motormen will have to be more careful than ever, or they will cease to be objects of public sympathy and altruistic sentiment. It is even an instance of poetic justice that the motormen who get most frozen are they who yield most to the bad American habit of being too much in a hurry, and these are the very men who most endanger the life and limb of the non-motormen.

For the world, including women and children, may for present purposes be divided into two great classes, the motormen and the non-motormen. How to enclose and protect the non-motormen is, after all, the great sociologic problem, for the non-motormen are multitudes, the motormen are but few, and the former are often quite valuable to society, many of them being highly respected and useful. They are often students and scholars, eminent divines, lawyers, doctors, judges, and merchants. Such men are often wrapped in "brown studies" in all weathers, and oblivious of danger. They may even be cogitating the invention of trolley-fenders, and meet death in such abstraction.

The non-motormen should be especially protected when, as is often the case, they are feeble and perhaps crippled by wounds received in the army or elsewhere. Their sight may be impaired also by long use of the microscope in pursuit of deadly microbes, or from too long reading to sick persons, or the study of the canals of Mars through the telescope, or other equally benevolent pursuits. They must be cared for and not left exposed to the inclemency of the trolley and its motorman. For this is worse than the winter-wind, just as the winter-wind is not less unkind than man's ingratitude. For the trolley blows and whistles and creaks and rattles all the year, while Boreas and Auster and their fellows have but a short season; and these worthies only nip the nose and cheeks and cover the moustache with frosty rime, and stiffen the toes and fingers with cold. But the trolley when it strikes is very striking, and when it nips it nips the head from the shoulders: and when it stiffens it stiffens the body with all its limbs and members, making it what is technically termed "a stiff."

Various plans have been suggested to save the non-motormen—one is a wire cage with spring buffers, which is ungainly and might tend to create a sense of isolation and a class-feeling which is so much to be deprecated. Feather cushions strapped on the prominent points of the valuable citizen have been advocated. But the plan that has received most favor is that of a well-known electrician, who proposes to have each citizen carry a small battery and sound an electric gong every few seconds to warn the motormen. This seems practical, and when once the custom of wearing the battery becomes universal it could be further utilized to furnish an electric light, and illuminate the citizen at night, thus adding another element of safety. Infants and the aged could carry lights of a peculiarly striking character, or a variation of color or of the pitch of the electric gong, or both, might be employed to distinguish men of different pursuits. The Councilmen might carry a more automatic gong, for instance, and more numerous electric lights. This idea is more captivating the more the mind dwells on it. One can in fancy imagine the streets of the future resounding by day with myriad bells of varied tone, and these isolated notes by a great natural law would seem to group themselves in a mysterious rhythm and harmony, while at night the added gleam of innumerable, ever-moving colored lights would indeed lend to the now prosaic world a missing tinge of paradise.

Serious Infection Through Slight Wounds.—The possibility of the development of profound constitutional phenomena as a result of general infection of a non-specific kind through local lesions has long been recognized and appreciated. When the chain of events in this process was not so well understood as it is now the condition was in a vague way designated "blood-poisoning." At a later date the new pathology coined the term "septicemia," and its sub-divisions "septic infection" and "septic intoxication;" while these in turn have with further progress been supplanted by the terms "infection" and "intoxication" without special qualification.

"Infection" may be defined as a morbid condition dependent upon the presence and activity of pathogenic microörganisms, and may be local or general. "Intoxication" is practically synonymous with "poisoning." It may be due to the presence in the circulation of the toxic products of an infective process, local or general, or of any other substance capable of causing toxic manifestations. It may thus be due to alcohol, to lead, to arsenic, and to other substances, as well as to the toxic products of the vital activity of micro-organisms, whether generated in the laboratory or in the human body.

Of the two conditions under consideration we have many examples. Most infectious processes—perhaps we would be justified in saying all—are at the outset local. Some remain so; others become general. All, however, are attended at some stage with intoxication. These statements are as true of tuberculosis as they are of tetanus, of diphtheria, of cholera, of typhoid fever, and of pyemia. Syphilis must be considered an infectious disease, although its cause has not yet been isolated with certainty. The distinctive characteristics of infectious diseases are their transmissibility and the possibility of indefinite multiplication of their cause. Most of the infectious diseases destroy by intoxication, rarely by general infection.

The propositions that have thus far been made would seem to apply equally to the malignant neoplasms. While in these the etiology remains an unsettled question, it is generally admitted that such growths are primarily local, and that metastasis can be prevented by timely and radical extirpation of the original growth. These facts in a measure justify the classification, tentatively at least, of malignant tumors, particularly carcinoma and sarcoma, among infectious diseases. That such new formations do give rise to manifestations of general intoxication is a well-recognized clinical fact, and one of the most pronounced phenomena of which is the almost invariable cachexia that appears.

As illustrative of some of the points referred to in the foregoing remarks we wish to cite an interesting observation in which acute nephritis developed in the sequence of staphylococcous infection of slight wounds upon the hands.

SACAZE (*Revue de Médecine*, 1895, No. 2, p. 136) has reported the case of a man sixty-five years old, and previously well, who in handling lumber received slight wounds upon the dorsum of each hand, which in the course of a few days became inflamed and angry. At the same time profound constitutional symptoms appeared, and the clinical picture of an acute nephritis developed, leading to a fatal issue. It is believed, and reasonably, it appears to us, that the train of events was due to general infection with staphylococci, which were found in the discharge from the slight wounds upon the hands.

The Medical Department of the University of Michigan.—As a way out of the difficulty in the department of medicine and surgery of the University of Michigan occasioned by the existence of a so-called homeopathic department in addition to the regular department of medicine and surgery, the Chairman of the Committee on Medicine, to which was referred the communication of the dean of the homeopathic department, proposing a form of amalgamation, as outlined in THE MEDICAL NEWS of March 2, 1895, p. 248, recommends the establishment of a chair of homeopathic materia medica and therapeutics in the regular department of medicine and surgery. It is intended that this course shall be obligatory on all students of medicine, but that no division of clinical chairs should be made according to so-called "pathies." The best men should be selected for the chairs, irrespective of dogma or peculiarity of practice. It is pointed out further that the "pathy" element exists only upon the one side, allopathy being a term in employ by sectarians and no accepted by regular practitioners. As is pointedly remarked, the assumption of sectarian designation should not be a sufficient reason for appointment to a chair of surgery or gynecology or other practical teaching position. Educational institutions under the care of the State and sustained by State funds should be administered in the interests and for the welfare of the entire community, and not for the benefit of any one class or portion. The only intelligent course for the Board of Regents of the University of Michigan to pursue is that proposed by the Chairman of the Committee to which the matter was referred—*i. e.*, the establishment of a course of lectures on homeopathic materia and therapeutics in addition to and in conjunction with the regular course of medicine and surgery.

Leukocytosis in Hypertrophic Cirrhosis of the Liver with Chronic Jaundice.—The chronic interstitial inflammation of the liver commonly designated cirrhosis, together with its morbid anatomy and characteristic symptomatology, has become well known since the time of Laennec. It is, however, only within a comparatively recent period that another form of a similar process in the liver has been described by Hanot, under the designation of hypertrophic cirrhosis. The former of these has further, for purposes of distinction, been called the portal form, the latter the biliary form, from the respective distribution of the morbid process. The clinical differentiation is based upon the diminution in the size of the liver (preceded or not by recognizable enlargement), and possibly similar changes in kidneys and spleen, together with the early appearance of ascites, and the late appearance of jaundice, in the one condition, and the progressive enlargement of the liver and also of the spleen, together with early and pronounced jaundice, and the absence or later appearance of ascites, in the other condition. As an additional diagnostic feature Hanot and Meunier (*Compt. Rend. Hebdom. des Séances de la Soc. de Biologie*, 1895, No. 3, p. 49) call attention to the occurrence of leukocytosis, which they found a constant feature in three cases of hypertrophic cirrhosis of the liver with chronic jaundice, in the absence of any extra-hepatic inflammatory process. Isolated observations by others point also to the existence of the same association. The number of white cells averaged 15,500 per cubic millimeter, as compared with 6000 under normal conditions. In other varieties of cirrhosis no increase in the number of leukocytes was observed. This peculiarity of hypertrophic cirrhosis is considered evidence in favor of its infectious nature and a means of differentiation.

The Complications of Influenza.—We are now emerging from the fifth recrudescence of the pandemic of influenza which has been followed by such devastation and which has left so much wreckage in its wake. Different epidemics have presented somewhat differing symptom-groups, and the fatality of the disease seems somewhat to have subsided, although its virulence otherwise appears to have been fairly well maintained. The nervous system has played a large and important part in the symptomatology of the disease in the successive outbreaks, and the related sequelæ have been numerous and serious.

Sansom (*Liverpool Medico-Chirurgical Journal*, 1895, No. 28, p. 118) has recently reported three cases of influenza followed by disease of the spinal cord. The first occurred in a woman, fifty-one years old, in whom a second attack of influenza was followed by paralysis of the arms and legs, with pains, tremors, rigors, and erratic temperatures, with paralysis of the thoracic muscles, arthritis, double optic neuritis, and death. The second occurred in a woman, twenty-two years old, was complicated by arthritis, presented dysesthesia and paralysis of the arms and legs, with tremors and signs of muscular incoördination, and terminated in recovery. The third case occurred in a rheumatic subject and was complicated by the development of paralysis of the arms and legs, with tremors and signs of rigidity and wasting, and also pains and dysesthesia, with symptoms of disturbance of the vagus, and finally mono-arthritis. Improvement followed treatment.

Optic Neuritis in the Sequence of Scarlatina.—A certain parallelism exists in the symptomatology of the various infectious diseases, and the nervous system seems peculiarly susceptible to the action of the poisons generated as a result of the morbid process. The optic nerve not rarely suffers in this connection, even when other parts escape. These points are well illustrated in a case reported by D'Oench (*American Medico-Surgical Bulletin*, 1895, No. 4, p. 238) at a recent meeting of the Section on Ophthalmology and Otology of the New York Academy of Medicine. In a boy, seven years old, sight began to fail during convalescence from an attack of scarlatina. The pupils were dilated, but reacted feebly to light. Both eyes presented optic neuritis, more marked in the left. The boy was drowsy and the back of the neck was tender. The urine presented no abnormality. As improvement failed to follow the administration of calomel, increasing doses of potassium iodid were directed. After a while perception of light returned in the right eye, and some days later large objects could be perceived and the pupil responded to light. In the course of a month the hemorrhages that had been observed had entirely disappeared, and vision was almost entirely restored in the right eye, though entirely absent in the left. Both papillæ were markedly atrophic. After the lapse of a year the condition of the left eye was unchanged.

Teaching Old Nerve-centers New Tricks.—Veterinary-Captain F. Smith, at the last meeting of the British Association, recited a suggestive experiment carried out upon two horses afflicted with laryngeal paralysis, the object being to secure a new nerve-supply. This was sought in the spinal accessory. The recurrent and spinal accessory were exposed and divided, and the proximal end of the accessory was sutured to the distal end of the recurrent. The results were very encouraging. In one case there was relief of the harshness in breathing and the dyspnea, and in the other the noisy breathing persisted but the distress was relieved. It would, therefore, appear that a nerve-center may possibly be educated to perform a duty for which it was not originally intended.

Picking of the Bed-clothes in Disease.—Sir Benjamin Ward Richardson (*Asclepiad, second quarter*, 1894–'95, p. 159) points out that while picking of the bed-clothes in advanced stages of disease is in general indicative of dissolution, it is not invariably so, and may be followed by recovery. The phenomenon is peculiar in that it is always the same in character. It appears in both hands as a sharp movement, as if it were intended for the picking up of something which the patient sees or thinks he sees, but of which, as a rule, he later has no recollection. Jactitation of the muscles of the forearms and hands is the most common accompanying manifestation, although there is no proportionate relationship or intensity between the two. The phenomenon is not distinctive of any particular morbid state or disease, but usually appears in connection with gradual sinking or collapse, and must be considered an ill prognostic omen.

Tracheotomy and Diphtheria.—Sir Benjamin Ward Richardson (*Asclepiad, second quarter*, 1894-'95, p. 161) offers the suggestion that tracheotomy for the relief of laryngeal stricture in the course of diphtheria is a curative measure not merely by its admission of air into the lungs, but by allowing such admission without the passage of air over a decomposing surface.

CORRESPONDENCE.

LONDON LETTER.

Death of Mr. Hulke—The Royal Society—Death of Sir William Savory and of Mr. Hake—Honors to Medical Men—The Antitoxin Treatment of Diphtheria—The Epidemic of Influenza.

Less than eighteen months ago the President of the Royal College of Physicians, Sir Andrew Clark, was struck down in the midst of his work. Now the Royal College of Surgeons has lost its official head in a manner almost as dramatic. Mr. Hulke was to have delivered the Hunterian Oration at the College on February 14th, and he had arranged for its publication in the *British Medical Journal* of February 23d. The oration duly appeared, but before that date the "blind fury with the abhorred shears" had snipped the thread of the orator's useful and laborious life. Mr. John Whitaker Hulke had stood by the deathbed of the great Duke of Wellington, who was a patient of his father, and had been a prominent figure in the medical profession of this country for more than thirty years. Though best known as an ophthalmologist, he was an excellent all-round surgeon, and but for a certain infirmity of temper he would probably have been the leading consultant in London. Those, however, who most fully recognize the sterling qualities of the man acknowledge that he was, as Thomas Carlyle's mother said of her distinguished son, "gey ill to live wi'" in a professional sense. He brooked no brother near his throne; in fact, he owed his death to his characteristic unwillingness to delegate any part of his duties to colleagues. He insisted on leaving his bed on one of the coldest nights of this bitter winter in order to operate on a case of strangulated hernia at the hospital. This operation is looked upon in the London hospitals as a perquisite of the assistant surgeons if the emergency occurs at night. Mr. Hulke's somewhat jealous insistence on his prerogative was rather what the French call the "defect of his virtues" than a fault, and though we may regret that he should have exposed himself to a totally needless risk, we cannot refuse a tribute of admiration to a man who fell a victim to his own sense of duty, however mistaken we may consider it to have been.

In Mr. Hulke the English profession has lost a man of the highest professional character, one whom, in these days of self-advertisement and questionable short-cuts to success, it can ill spare. In addition to his eminence as a surgeon he had won an honorable name by his paleontologic researches. He was twice chosen President of the Geological Society. He was also a Fellow of the Royal Society, a learned body which, though not so very long ago open to mere rank and influence, now guards its portals so strictly that admission is the seal that stamps a scientific reputation as genuine. This distinction is becoming much rarer among surgeons than it was even a few years ago. The Royal Society does not recognize mere professional work, however good of its kind, as a title to membership, and the younger race of surgeons who are nothing if not "practical" have probably discovered that pure science does not "pay." It is possible also that the power of selection is somewhat too much in the hands of one man as far as medical candidates are concerned. Professor Michael Foster is admittedly one of the brightest lights of the physiologic firmament, and he has quickened the Medical School of the University of Cambridge into new and vigorous life. As Secretary of the Royal Society, however, his activity has sometimes been less happily directed, and rightly or wrongly an impression exists that the scientific Peri who has not found favor in the Secretary's sight is doomed to wait disconsolate at the gate of the paradise of science.

Among other notable members of the profession, who have recently passed away are Sir William Savory, a former President of the Royal College of Surgeons, and for many years surgeon to St. Bartholomew's Hospital, and Dr. Thomas Gordon Hake, a cousin of General Gordon, the hero of Khartoum, and a poet whose powers were very highly thought of by men like Dante Gabriel Rossetti, Algernon Charles Swinburne, and Theodore Watts.

Oliver Wendell Holmes speaks of there being a whole museum of wigs, and masks, and lace coats, and gold sticks, that are still used in the Old World, and which the enlightened citizens of the United States laugh at honestly without affectation. In this museum the "Autocrat" would doubtless have placed titles, though, by the way, many of his countrymen who happen to be fathers of what the Scotch call a "lass wi' a tocher" do not seem altogether to share his contempt. There are two seasons—the New Year and the Queen's birthday—when a wave of excitement passes over a number of more or less worthy folk who have a keen sense that their services deserve public recognition. At these times a few titles are flung to the more favored or more persistent claimants—*pour encourager less autres*. One or two of these glittering baubles are usually given to the medical profession.

To practising physicians such distinctions have a solid value in this snob-ridden country; a title is an excellent advertisement, and vulgar rich people pride themselves on "never having anybody lower than a Bart."

when a consultant is wanted. The Queen is not always particularly fortunate in her selection of those whom she delights to honor—at least in the opinion of those who are passed over. The keeper of the royal conscience in the matter of medical dignities is her trusted physician, Sir William Jenner, a man against whose uprightness and integrity not even the *invidia medicorum*, which is the worst form of envy, can find anything to say. If in the apportionment of titles he has seemed to show a preference for the men of his own school (University College), that is probably due to the fact that he has had better opportunities of forming a judgment as to their merits than in the case of others whose work has fallen less directly under his eye. There can be no stronger proof of the real eminence of Sir Russell Reynolds and Sir John Erichsen, the two members of the medical profession whom the Queen chose to be the recipients of "New Year honors," than the fact that though both belonged to the privileged school of University College, the distinction conferred upon them has been universally recognized as due entirely to their merits. In the case of Sir John Erichsen in particular the only reason for wonder is that a title which is the highest public recognition accorded to the art of healing in this country should have been so long withheld. Sir John might say with old Samuel Johnson, that the honor, such as it is, has been delayed till he is past caring for it, or, at any rate, till he is solitary and cannot share it, for he lost his wife last year, and has no children around his desolate hearth. He is now seventy-seven years of age, and has retired from active practice. He still, however, takes an interest in matters affecting medical education and in the furtherance of the scheme of a real living and teaching university for London; and he has just been reëlected President of University College. A new (tenth) edition of his well-known text-book, *The Science and Art of Surgery*, is now in press; the first volume has already been issued. The first edition was published in 1853, and in this country alone some forty-thousand copies have been sold. In the United States the sale has also been very large. During the Civil War a copy of the work was issued by the United States Government to every medical officer in the Federal Army. It has been translated into German, Italian, and Spanish, and in the last version it has had a wide currency in South America. To be the author of such a work is a far higher distinction than the title of "Baronet," which is often given by the powers that be to supporters whose political enthusiasm expressed itself in liberal contributions to party funds.

Sir Russell Reynolds is President of the Royal College of Physicians, a dignified post, which almost demands that its occupant shall be a Baronet. The man is, however, in himself worthy of any honors that the Queen can bestow on him. His indifferent health has of late years made him somewhat less prominent in the public eye than his position in the esteem of the profession would have led one to expect; and when the presidency of the Royal College of Physicians became vacant by the death of Sir Andrew Clark greatness was thrust upon, rather than sought by, him. He began his career with a singular stroke of luck, for he succeeded to the practice of Marshall Hall, whose daughter he married.

Among the questions of practical medicine which at present engage the attention of the profession the principal are the antitoxin-treatment of diphtheria and the influenza. The former is being tried all over the United Kingdom, and, as far as present experience warrants a judgment, there is a pretty general agreement that the remedy, when used under proper conditions, is a real specific, The disappointment that followed the tuberculin "fizzle" has made us rather shy of remedies belonging to the new therapeutic *régime*—especially such as are "made in Germany." This makes the footing that antitoxin is gaining for itself all the firmer, for it is conquering prejudice as well as scientific skepticism. The experiments are carried out in the light of day, and the results are faithfully reported, whether they make for or against the new remedy. As regards the antitoxin prepared in this country by the British Institute of Preventive Medicine, and by Dr. Klein, of St. Bartholomew's Hospital, no suspicion of any taint of commercialism is possible. It would be well if the same could be said as to the German supply; the price at which Behring's preparation was at first sold caused an outcry in the Fatherland, and now a patent for the preparation of remedial and immunizing substances, "the so-called antitoxins," in England has been applied for on behalf of "Hans Aronson, of 11 Fasanenstrasse, Charlottenburg, in the Empire of Germany, Doctor of Medicine." This exploitation of scientific research for personal profit is an ugly feature in the more recent history of German discovery, which may, perhaps, help to explain Virchow's unfriendly and suspicious attitude toward it.

As for the influenza, we seem, unhappily, to be no better able to deal with it in this, the fifth epidemic since 1890, than we were on the first visitation. It is to be feared that influenza has now taken its place as an *opprobrium medicinæ*. It is worthy of note that whereas in former epidemics the medical journals used to be full of remedies, each more infallible than the other, this time, so far, no new specific has been propounded, and the advocates of the old ones are more modest in their claims. Experience has, in fact, shown that the only remedy for influenza is to go to bed as soon as the disease has got one in its grip, and stay there till it has been shaken off. One curious feature in this, as in some previous epidemics, is the partiality which the influenza-bacillus manifests for our legislators—Lord Rosebery, the Prime Minister, and Mr. Arthur J. Balfour, the leader of the opposition in the House of Commons, are among its victims. At first the bacillus seemed to make a dead set at the supporters of the Government, and as the Liberals have a very narrow majority, it appeared not unlikely that they would be beaten by the influenza. They were saved by the bacillus in the nick of time turning its attention to the Tories.

NEWS ITEMS.

Sextuplets.—A well-authenticated case of sextuplets is reported from Italy. A woman, thirty-six years old, presented in the fourth month of her second pregnancy enlargement of the abdomen equal to that ordinarily observed at the end of normal pregnancy. While straining at stool on the one-hundred-and-fifteenth day the membranes ruptured, a foot prolapsed, and a fetus was delivered by a midwife. After a brief delay a foot was again brought down, and a second fetus was delivered, and successively a third, a fourth, a fifth, and a sixth. All of the children were born alive, and moved vigorously for a time. Four were males and two females. There was a single placenta and six amniotic sacs. Puerperal convalescence was practically normal. A year later the woman gave birth to healthy twins which lived.

Charcot Memorial.—The following is a statement of the contributions thus far received to the Charcot Monument Fund:

New York City.	
Dr. E. C. Seguin	$50
M. A. Starr	50
E. D. Fisher	50
C. L. Dana	20
C. A. Herter	50
A. Jacobi	10

Dermatologic Prize essay.—The annual prize of 300 marks offered by Professor Unna, of Hamburg, for an essay upon some subject in the domain of dermatology, not having been awarded during the year 1894, the amount has been doubled for the year 1895, the subject selected for consideration being: "An investigation as to the accuracy of the propositions recently made that callagenous, elastic fibers and fixed (pigmented) connective-tissue cells dip down into the normal prickly layer."

The competition is unrestricted. Essays must be submitted to Leopold Voss, Hohe Bleichen 34, Hamburg, before December, 1895, from whom also further particulars can be learned.

The Isabella Heimath is the name of an institution in New York dedicated to the care and maintenance of aged indigent persons, of chronic invalids, and of convalescents, without regard to sex, creed, or race. It is the outcome of an institution founded a number of years ago to serve as a home for indigent women. It was soon seen that a similar institution for indigent men was needed, and accordingly, in 1889, Mr. Oswald Ottendorfer erected and equipped a splendid building, at a cost of $600,000, and other members of his family contributed a large endowment-fund for its maintenance.

The Buffalo State Hospital.—Governor Morton has nominated the following as managers of the hospital: Daniel H. McMillan and Charlotte S. Williams, of Buffalo, reappointments. Charlotte Miller Glenny, of Buffalo, in place of Sadie R. Altman. John E. Pound, of Lockport, in place of John H. Meech. Roswell Park, of Buffalo, in place of William J. Tremaine. Joseph P. Dudley, of Buffalo, in place of Henry D. Kirkover. Frederick P. Hall, of Jamestown, in place of William M. Irish.

Extirpation of the Larynx for Malignant Disease.—At a recent meeting of the Académie de Médecine of Paris Prof. Péan presented a man from whom had been removed two years previously the entire larnyx, the superior portion of the esophagus, and the anterior portion of the pharynx for carcinoma of the larynx. Breathing, eating, and drinking were made possible with the aid of a suitable prothetic apparatus. The patient could, besides, make articulate sounds, so that speech could be understood.

The Passing of the American Lancet.—With the issue of the *American Lancet* for the current month Dr. Leartus Connor, after a service of nearly twenty-four years, retires from the editorial chair, and with his withdrawal the publication of the *Lancet* comes to an end. With the retirement of Dr. Connor and the passing of the *Lancet* medical journalism loses one of its cleanest and brightest monthlies and the medical profession a most conscientious and faithful journalistic representative.

The Ohio State Medical Society will hold its semi-centennial convention at Columbus, May 15th, 16th, and 17th. In addition to the usual scientific program a lecture by Dr. Judson Daland, of Philadelphia, on "Malaria," illustrated by lantern slides, will be a prominent feature.

The Society proposes to organize a committee on State medical legislation based upon representation from all the counties in the State.

As to "Books and Pamphlets Received."—Our announcements of books and pamphlets in THE MEDICAL NEWS are designed to give notice only of the most recent literature. We can, therefore, include in the list only those lately published. Many have been sent us that were several years old.

The Influenza Epidemic.—The mortality from influenza in London for the week ending March 2d showed a very considerable further increase. The deaths attributed directly to this disease, which had been 13, 24, and 111 in the three preceding weeks, rose to 296 during the week.

No Inter collegiate Foot ball at Harvard.—At a meeting of the Faculty of Harvard College, on March 19th, the opinion was, upon vote, expressed "that no student under their charge should be permitted to take part in inter-collegiate foot-ball contests.

The Kentucky State Medical Society will hold its fortieth annual meeting at Harrodsburg, June 12, 13, and 14, 1895.

Alphonse Guerin, a distinguished French surgeon, died recently at the age of seventy-seven.

THE TREATMENT OF FRACTURES.

BY F. E. BUNTS, M.D.,
OF CLEVELAND, OHIO;
PROFESSOR OF PRINCIPLES OF SURGERY AND CLINICAL SURGERY, MEDICAL DEPARTMENT WESTERN RESERVE UNIVERSITY.

WHILE many changes and many advances have been made in modern surgery, it is somewhat surprising, at first glance, to see how little has been the change in that part of it devoted to the treatment of fractures. This surely cannot be because other branches are of more importance, and consequently attract more attention and investigation, for this is almost the only ground on which physicians and surgeons meet on an absolutely neutral plane. The treatment of fractures is of as vital importance to the physician as to the surgeon; indeed, it is, perhaps, most frequent that the physician is called upon in emergencies of this character. Every one who professes to be a doctor, no matter what his specialty, is supposed to be able at least to mend a broken bone. Both the physician and the surgeon have been more frequently called to answer suits for malpractice resulting from the treatment of fractures than from any other cause, and while other operations bring much higher recompense, few are capable of bringing heavier losses. Thus, it would seem that if from no other consideration than a pecuniary one, the correct treatment of fractures would have become a study second in importance almost to none.

A badly managed case of pneumonia or typhoid may never live to complain, and an unsuccessful case of operation for strangulated hernia or for an inflamed appendix may join the silent throng, and leave behind but few to cavil at the physician's skill; but a badly managed fracture, with its deformity or impaired usefulness of limb, will stalk through the neighborhood and through the streets, threatening its unfortunate author, defaming his character, ridiculing with its mute witness his skill, and detracting by its persistent propinquity from his reputation not only as a bone-setter but as a physician or surgeon. The reason for this lack of progress is because the indications for the treatment of fractures have been so long known, so definitely and positively demonstrated, that little can be added. It is true that more or less varied means have been devised to meet these indications, but they have, after all, differed but little in principle. The mechanical genius and enthusiasm of some have given us many varieties of splints, but they were all practically made to fill the same indications, and succeeded in this aim about as well as those of less imposing curves and more modest pretensions.

The indications for the treatment of fractures are briefly as follows: Reduce the fragments to their proper places; retain them in position; combat inflammation; restore function; relieve pain.

I shall take up the several indications in turn. First, reduce the fragments to their proper place.

At once the question arises, When should this be done? Is it best to extemporize something at the scene of the accident, or is it best to wait until the patient is at the office, or his home, or in the hospital? Obviously this depends largely upon the nature of the fracture. An uncomplicated fracture of the radius or ulna, or one of the tibia, may often be promptly adjusted and held in place by the most simple of extemporaneous splints, but, generally speaking, it is best to wait till the surroundings are more favorable for efficient work; particularly is this the case in fractures of the femur or of any bones in which the break extends into a joint. There should, however, always be a provisional splint or support applied before the patient is moved. Even without the reduction of the deformity, the support of a straight board, or shingle, or pillow, or layers of pasteboard, or the many other devices that may be at hand, will give immense relief to the sufferer, and perhaps prevent the fragments from perforating the skin, or from lacerating still more the already goaded muscles. It is often surprising to find with what facility and freedom from pain an unadjusted fracture may be handled and the patient moved when supported by the rude contrivance we may find at hand.

Again, the question of time may present itself in another light. Suppose the limb is swollen, its normal outlines lost, and the pain intense. Should an attempt be made to adjust the fragments, or should the limb be left without support of splints, and simply treated with local applications to reduce inflammation, in hopes that when this subsides a better reduction may be accomplished? There can be little question in many of these cases that the reduction of inflammation becomes the all-important indication, but we must remember that the most important thing in the treatment of acute inflammation is rest; without it local applications of heat or cold, or arnica, or lead and opium, can but prove unsatisfactory. And how are we to obtain rest? Surely the simple laying of a limb upon a pillow will not suffice. The slightest move of the patient, the incautious meddling of the attendant, may send the jagged ends of bone into the tortured tissues, and add new fuel to the flames already burning.

I believe that these cases demand splints. I grant that it is often impossible to restore the fragments to their natural position, except under chloroform, and in these cases an anesthetic is nearly always needed, but the limb can be nearly straightened, the muscles can be put in a position favorable to decrease of tension, a crushed joint may be put at rest; retention-splints can be gently applied, the limb elevated, and then, if you choose, local applications to reduce inflammation may be applied. I say, if you choose, because in my own experience it has been comparatively infrequent that other means than rest and elevation have been demanded.

"The reduction of fragments to their proper places" appears best on paper or in text-books; what we actually do is to restore as nearly as possible the normal outlines of the parts, and while this result is most frequently obtained, yet the actual restoration of the fragments to their normal relations is, I presume, of rare occurrence, except possibly in transverse fractures.

The general principle underlying the reduction of deformity caused by fracture is that of extension and counter-extension, and I have not infrequently heard both physicians and patients tell how hard a pull it was, or how many it took to get the bone straight, and of the exquisite anguish suffered by the patient while this torture was going on. I must confess I cannot understand why this should be. It would seem that in these cases, in which extreme suffering has made the muscles tensely contracted, it would be far better to give chloroform; under its soothing influence the muscles relax, and a formidable operation is converted into a simple moulding of parts into their normal relations. I believe that the more general use of chloroform would lead to better results in the treatment of fractures, for under its influence, particularly in fractures involving joints, the exact lesion is more readily made out and more accurately adjusted, and it may be well to draw attention here to the fact that when once properly reduced the tendency to displacement subsequently is but slight.

Aside from the danger attached to all anesthetics there is but one objection to the use of chloroform, and in the hands of the thoughtful or careful physician or surgeon even this does not hold; this is a tendency to too much manipulation because the patient does not feel it. We must remember that, even though unconscious, every motion of the rough ends of bone may be lacerating nerves, arteries, or muscles, therefore the least possible manipulation under any circumstance is most desirable.

It is upon the second indication for the treatment of fractures, that of maintaining the fragments in position, that the ingenuity and thought of our profession have been bestowed. For generations books have teemed with the devices of mechanics turned doctors or doctors turned mechanics, and well may we of to-day congratulate ourselves that these formidable creations of the past, however well they may have filled the indications in the hands of their inventors, are no longer considered a necessary part of our armamentarium. If there has been any advance in this part of the treatment of fractures, it has been in the return to a more simple means of maintaining the reduction of the fractures.

The invention of new splints and the naming of them after their ambitious inventors are deservingly falling into desuetude, and a splint made with projections and depressions, curves and angles to fit broken bones deeply seated or surrounded with soft tissues no longer appeals to the judgment of the physician or reaps harvests for the maker. Strips of basswood and "Buck's extension" will suffice, even in the hands of one who is not a mechanic, to treat almost any fracture except those involving joints, and even these when not amenable to treatment in the extended position are best treated by the simplest and least complicated of angular splints.

One cardinal principle must obtain, and that is, having decided the best position for the limb, to use that splint, whether internal or external, anterior or posterior, dorsal, palmar, or lateral, that best holds the fragments in the desired position, and no preconceived notion should make us use a certain form of splint when another will better fulfil the indication.

In regard to fixed dressings, for example those of plaster, I have but a few words to say. Unless the injury to the soft parts is very slight, and unless the parts can be quite accurately coaptated, and unless, further, the case can be under very close observation for the first week or ten days, I am wholly opposed to their use. The danger of gangrene from pressure in an acutely swollen leg, or the displacement of fragments as the swelling subsides, makes their disadvantage very serious, and whatever good results may have been obtained by those who use them, it yet remains to be shown that the non-permanent method is not safer, and its results not so good or better.

Meddlesome interference with fractures is to be deprecated, but still more are we to censure that fear or lack of knowledge that permits the splints as first applied to remain on indefinitely till union is accomplished. I have seen numerous instances in which, rather than disturb a fancied good setting, the limb has swollen about the splint, intense pain has supervened, and yet as long as vitality showed itself in finger-tips or toes the splints remained, till finally, when at last removed, a decubitus had formed extending down to the bone or tendons, or a tendo-synovitis established that has perhaps almost permanently impaired the use of the limb.

A fracture perfectly set shows but little tendency ordinarily to be again displaced, so that with average care the splints can be removed on the first or second day and the adjustment corrected or verified without pain or danger to the patient, and this, I believe, should, with few exceptions, be a routine practice. It is to be remembered that at about the end of the first week actual repair begins, and we should be certain before this time that the fragments are in the position that we desire them to be when union is completed.

Closely allied to the maintenance of fragments in position is the combating of inflammation. One of the greatest aids to this end is the reduction of the fragments to their place and maintaining them there, thus relieving the soft tissues of a source of constant irritation. Elevation, by bringing into use the force of gravity, and thus assisting in the unloading of over-charged vessels, is of great importance; general position also adds its share in securing the comfort of the patient.

Of all local applications, heat and cold demand the greatest consideration and confidence. It has, I think, been altogether too common to decry the use of cold in treating inflammation resulting from fractures. The same judgment is here required as to whether cold or heat is best as is required in the consideration of the treatment of any other injury. Some cases, such as those occurring in the aged or in delicate or rheumatic persons, at once suggest to us the impropriety of using cold; while in the healthy or in the plethoric, particularly if the fracture extends into the joint, ice-cold applications are of the greatest benefit, and their use cannot be too strongly urged. Of course, a time comes when the continued use of either heat or cold is not indicated; but this is a question whose decision must be made by the attendant, and for which no fixed rules can be laid nown.

The majority of topical applications owe their value here, as they do in other inflammations, to the evaporation and consequent cooling of the surface that occur when they are used, and they are therefore to be regarded as entirely secondary in efficiency to the use of cold or heat.

I here mention the relief of pain as one of the indications in the treatment of fractures, because I desire to emphasize the fact that properly adjusted fractures rarely cause much pain, and the administration of an anodyne for this purpose, except possibly during the first day, is not ordinarily necessary. Persistent and excruciating pain is always, in my own practice, an indication for prompt removal of dressings and careful revision of the splints, paddings, and bandages, or the readjustment of the fracture. A very slight change in the dressing will often give instant relief from pain, and if the importance of this fact were more generally appreciated there would be less frequent administrations of anodynes and more careful investigation of the dressings, and consequently more carefully adjusted fragments. Serious pain at the seat of fracture persisting after the second day is almost invariably due to a faulty replacement of fragments, and is in all cases an imperative indication for readjustment of splints or bandages.

The last indication, that of restoration of function, must be kept in view from the very first. Not every fracture will permit of complete restoration of function. Important structures may have been injured or joints entered that may render it obvious from the start that complete restoration can never occur; but we must always strive for the best under existing circumstances. The causes of impairment of function are various, and among the more obscure ones are to be mentioned injured nerves and compressed and obliterated vessels. The most common cause in uncomplicated cases, however, seems to be long-continued fixation of the neighboring joints, rendering them stiff and painful when the time comes for using them. Fortunately, as this is the most common cause, so it is the one most easily counteracted, and that by the use of frequent massage and early passive motion of the joints. I grant that this consumes more time than we often feel inclined to bestow, but the benefit to be derived is none the less positive. In connection with this I wish to urge the early abandonment of splints. Certain complications, such as non-union or fibrous union, may interfere with all rules; but, as a general statement, from two to three weeks for children, and from three to four weeks for adults, is a sufficient length of time for a splint to remain on. This would hardly apply, however, to fractures of the femur, in which it is not infrequently necessary to maintain the splints for six or eight weeks, or even longer, though here too the general law holds that dressings should be removed at the earliest possible moment and massage and passive motion instituted. While early passive motion in cases of fractures extending into the joint is opposed by some, and while there undoubtedly exist some theoretic objections to it, yet as the outcome of practical experience I can most heartily recommend it, and constantly make use of it in my own practice.

The discussion of the treatment of compound or other than simple fractures, or of the many complications that may occur at the time of the injury or subsequently, is not attempted in this paper. I have endeavored to confine myself solely to the general indications for the treatment of simple fractures, and as a summary, desire to call attention to the following propositions:

1. The indications for the treatment of fractures are]positive and fixed.
2. All fractures should be adjusted at the earliest possible moment consistent with the obtaining of proper appliances or assistance.
3. We should not wait for inflammation to subside before placing the fracture in some kind of a retention-apparatus or splint.
4. Chloroform should be administered more frequently to facilitate diagnosis and adjustment.
5. When properly reduced there is comparatively slight tendency to redisplacement.
6. Simple splints are to be preferred to moulded ones.
7. Use that splint that best fulfils the indication, regardless of preconceived ideas.
8. Non-permanent are ordinarily to be preferred to permanent dressings.
9. Dressings should be opened up and fractures examined not later than the second day.
10. Rest and elevation are the best means of combating inflammation.
11. Cold is not contra-indicated in robust patients, particularly if the fracture extends into a joint.
12. Pain is best relieved by revision of the dressings.
13. Early passive motion and frequent massage are the best means of restoring function.

THE TREATMENT OF EPILEPSY.

BY W. H. HATTIE, M.D.,
ASSISTANT SUPERINTENDENT, HOSPITAL FOR THE INSANE, HALIFAX, N. S.

THE term auto-intoxication has become very familiar to physicians within recent years. Bouchard's work upon the subject has circulated widely, and has indeed done much toward the modification of our views of certain disease-processes. After many years of patient research morbid anatomists have been compelled to admit that it is possible for a man to suffer for years from a disease which may manifest an almost constant symptomatology, which may cause an immense amount of suffering, which may even incapacitate him entirely from his daily vocation, and yet which may leave absolutely no trace of disorganization of tissue to be detected by our present methods in pathologic investigation. There are several common disorders which are so characterized, and which have, in confession of ignorance, been classed as "functional." It would appear now that it is in this class of diseases the theories of auto-intoxication find especial adaptation, and probably no disease indicates more strongly the likelihood of a species of self-poisoning than that peculiar manifestation of disordered nervous action known as epilepsy. As yet, unfortunately, we have no definite proof that can be brought forward in support of the theory; but the theory is really so plausible, and it seems to offer such reasonable explanation for otherwise inexplicable conditions, that we bid it welcome.

The term auto-intoxication is not, perhaps, a good one. It scarcely expresses all that it is intended to imply—that the poisoning may not be due alone to defective elimination of toxic products of man's own metabolism, but that it may also depend upon the excessive absorption, particularly from the digestive tract, of the products of the bacteria, etc., which, under any conditions, are present there. "Insufficient elimination" possibly covers the ground better, but is less wieldy than the generally used term.

We look upon convulsions, no matter what their nature, as the result of a sudden and violent discharge of nervous energy from the cells of one or other portion of the central nervous system. As to the cause of this discharge, we have no definite knowledge. It is very probable indeed that there is a lack of inhibitory power in the motor cells, but there must be a pathologic state underlying this lack. The microscope has given no positive information on this point. Bevan Lewis, it is true, has claimed that by adopting a certain technique, a fairly well-defined and nearly constant vacuolation of the nuclei of the second layer of cortical cells can be made out, in the post-mortem examination of an epileptic's brain. But other observers have detected similar changes in the brain of animals after excessive fatiguing exercise. It seems reasonable, therefore, to assume that the condition that Lewis describes is consequent upon rather than causative of the epileptic discharge. I think it is much more than likely that if convulsive seizures are due to any morbid anatomic condition, the very perfect apparatus with which we are now provided for the study of the tissues would long ere this have permitted us to demonstrate such a condition so conclusively that there could be no room for dispute. We are, therefore, simply driven to the conclusion that the pathologic state underlying these seizures cannot be histologic, and that we must look in some other direction for the discovery of the cause of these very distressing "nervous storms."

It is quite natural, in this day, for us to turn our attention to the chemic side of the problem of life. The recent advances in the chemistry of both physiologic and pathologic processes have not been less wonderful than they have been practical, and we are led to expect much from the workers in this field. But we need scarcely take into account the most recent work in order to form a very good hypothesis as to what constitutes the condition underlying the convulsive habit. Even with little knowledge, we can readily conceive that the lack of inhibitory power which (in "idiopathic" epilepsy) we believe to exist in the motor cells may be the result of mal-nourishment consequent upon the insufficient removal of some waste product (*i. e.*, toxic material) which, as a mild but constantly acting irritant, tends to make unstable the cerebral cells. I confidently believe that it is toward the discovery of such toxic material we must direct our attention if we are to find the cause of the trouble.

Perhaps the case is stated rather bluntly when the instability is attributed merely to a defect in elimination. There may be an excessive production of the toxic material. This question, however, does not affect the treatment which the assumption suggests. If it is granted that toxic matter is allowed to accumulate, we can readily understand that a certain point will in time be reached when the nervous centers can no longer stand the pressure, and when a convulsion will be determined. Or it is quite conceivable that the cells, rendered unduly irritable by the continued presence of the effete material in quantity which is insufficient in itself to cause discharge, may react violently to some slight external stimulus (as a loud noise or sudden flash of light) which ordinarily would have no such effect. In either case, the discharge is followed by a temporary restoration of cell-stability. This, I believe, is due to the fact (ascertained definitely by Horsley) that the brain is hyperemic during a convulsion—a condition which certainly must aid in the elimination of the toxic material. The increase in the urinary secretion, so frequently noticed after a fit, would also appear to indicate an extra elimination of effete tissue-products.

The theory merely supposes a close analogy between the convulsions of epilepsy, of uremia, of asphyxia, etc. No matter what muscles are implicated in a convulsion, and no matter what we have supposed the underlying cause of the convulsion to be, we have been accustomed to regard all convulsive seizures as due to abnormal functioning of cells in some part of the central nervous system. The cause of this abnormal functioning is not yet apparent, but there is much reason to suppose that it is due to some process of auto-intoxication.

Physiologic experiment has shown that certain substances found in urine, as kreatin, kreatinin, etc., when sprinkled over the motor cortex of experimental animals, will induce convulsions that are followed by coma. Normally, from nervous tissues certain chemic substances may be isolated which bear close resemblance in composition to kreatin; in fact, this agent itself has been separated, as also have xanthin, hypoxanthin, etc. It is interesting in this connection to note a case not long since reported in The Medical News, by Dr. B. K. Rachford, of Cincinnati, in which there were peculiar epileptoid attacks, and in which it was found that hypoxanthin appeared in marked excess in the urine.

In a *Note on Convulsive Seizures*, which I recently published, there occurs the following:

> "Our knowledge enables us to classify convulsions into those that *are* and those that *are not* due to some evident irritant. Those fits following trauma of the brain, those associated with tumor, abscess, or other condition in which structure is disturbed (as in apoplexy, meningitis, general paralysis of the insane, etc.), class under those due to an evident irritant. The so-called idiopathic epileptic fits, major and minor, the convulsions of hysteria, etc., might be placed in the list of those in which there is no evident irritant. And in some conditions that have long been regarded as due to the retention of effete matters in the system—as in what has been called uremia, as well as in the early stages of many acute disorders regarded by modern pathologists as toxic (bacterial), we find convulsions to be a frequent and prominent symptom. It is true that these convulsions differ materially from one another in their appearances, but the differences are really minor, and depend upon the situation of the cells in which the discharge of nervous energy originates. I think it is reasonable to suppose that in every case the cells are excited into discharging—or at least made extraordinarily unstable—on account of irritation, whether that irritation be evident as a tumor or gross lesion of some kind, or whether it be the more subtle but equally capable effect of some retained poisonous secretion."
